RESULT OF THE FORECAST OF CHOLERA, SMALLPOX AND PLAGUE IN INDIA IN 1932 AND FORECAST FOR 1933*

By Sir LEONARD ROGERS, K.C.S.I., M.D., F.R.C.P., F.R.S.
MAJOR-GENERAL, I.N.S. (ret'd.)

THE analysis of the results of my forecast of the incidence of cholera, smallpox and plague in 1932, recorded below, shows it to have been the most accurate of the three yet issued, in spite of the well-distributed rains of 1931 having made a forecast difficult. As the two previous forecasts also proved more correct than I had dared to hope, it now appears to be evident that my three years' very laborious studies of the incidence of these epidemic diseases in relation to the climatic conditions in India during the last sixty years have provided data from which moderately-accurate and practically-useful forecasts can be made several months ahead of the incidence of these three diseases. These forecasts are necessarily delayed and are less complete and up-to-date than they would be if they were worked out in India, instead of in London after the data have been received from India.

Result of cholera forecast for 1932

General Forecast.—'Not likely to exceed the average and will probably be well below it'.

Result.—Judging from the weekly figures nearly to the end of September 1932, and allowing for the average defect of the weekly returns below the final figures for each province during the three previous years, the total cholera deaths in India in 1932 do not appear likely much to exceed 100,000, unless Bengal, Assam and Madras show a considerable excess during the last quarter of the year. This rough estimate is about one-half the usual average for India, which would make the cholera rate in 1932 about the lowest since 1923. My forecast has thus proved correct, for all the provinces of India proper were much below the average except Bengal and Assam with approximately average cholera death rates up to September 1932. The detailed forecasts for the different areas may be recorded briefly as follows:—

Assam.—*Forecast*—low cholera in last four years, no epidemic likely, but some increase probable.

Result—slight increase in October 1931 to September 1932 on two former similar seasons.

Bengal.—*Forecast*—same as for Assam.

Result—not epidemic but slight increase on previous October to September rate.

Bihar and Orissa.—*Forecast*—average to low incidence.

Result—about average in Orissa and low in Bihar.

United Provinces.—*Forecast*—average to low.

Result—very low incidence.

Punjab.—*Forecast*—about the average.

Result—about the average for a non-Hardwar-Kumbh-Fair year.

North-West Frontier Province.—*Forecast*—cholera low for three years, some increase likely.

Result—prevalence again low except in August.

Sind.—*Forecast*—1931 rains failed so 'in 1932 increased prevalence is likely; this will be liable to reach epidemic proportions if the rains are also short in 1932'.

Result—fortunately the rains were in great excess in July 1932 and there was very little cholera in Sind. This was also largely due to the disease being nearly completely absent from the neighbouring areas of Multan in the south-east Punjab and from Gujerat to the south of Sind from which Sind could be infected. The failure of deficient rains to be followed by a cholera epidemic in the Bombay Presidency in years of very low cholera in India as a whole, such as in 1932, was pointed out in section IV of my memoir of 1928, 1904-1905 having been a typical example. Gujerat also escaped very lightly for the same reason.

Bombay Deccan.—*Forecast*—average to low cholera incidence in 1932.

Result—very little cholera.

Madras Deccan.—*Forecast*—1931 rains rather short, some increase likely over 1931 figures, but not epidemic.

Result—good 1932 monsoon rains and very little cholera, largely due to the disease having been nearly absent from the neighbouring divisions of Madras and the southern Bombay Deccan.

South-East Madras.—*Forecast*—about average incidence.

Result—incidence about the average.

North-East Madras.—*Forecast*—some increase on 1931, low incidence likely in 1932.

Result—low incidence in this division and in the Madras districts south of it.

Central Provinces.—*Forecast*—average to low incidence in 1932.

Result—low incidence.

The above data suffice to show that my forecast was very generally accurate in spite of the year having been a difficult one for that purpose.

Results of smallpox forecast for 1932

General Forecast.—The good 1931 monsoon and normal or high absolute humidities during the monsoon months, and especially in October, throughout north and central India, to which the forecast relates, indicate low smallpox generally in those areas during the smallpox season from October 1931 to September 1932.

* Received by air mail, 1st December, 1932.

Result—low smallpox generally in northern and central India.

United Provinces.—*Forecast*—low smallpox incidence in 1932.

Result—smallpox incidence very low in 1932.

Punjab.—*Forecast*—smallpox in 1932 below the average.

Result—below the average of recent years.

North-West Frontier Province.—*Forecast*—low smallpox incidence in 1932.

Result—about the average of recent years with the highest rates in June and July 1932 with favouring low absolute humidity in April to June 1932.

Central Provinces.—*Forecast*—low incidence in 1932 following very high absolute humidity in 1931 from July to October.

Result—very low smallpox in 1932 with a lower rate, as far as can be judged from the weekly figures alone available, than during the last nine years.

Bombay and Madras Deccan.—*Forecast*—average to low.

Result—low incidence.

Results of plague forecasts for 1932

Bihar and Orissa.—*Forecast*—hot season 1931 temperatures very high and saturation deficiencies high in Bihar, which alone suffers appreciably from plague, so 1932 plague incidence low.

Result—incidence very low, with an unprecedentedly rapid fall in April and May 1932 in relation to exceptional high mean temperatures and saturation deficiencies in March to May.

United Provinces.—*Forecast*—hot weather temperatures and saturation deficiencies very high, incidence likely to be below the average.

Result—incidence low.

Punjab.—*Forecast*—hot season temperature high and unfavourable to plague but saturation deficiencies low and favourable; incidence about average.

Result—incidence about the average of the last few years.

Central Provinces.—*Forecast*—saturation deficiencies and hot season temperature high and unfavourable to plague; 1931-1932 incidence below the average.

Result—about the average of the last few years and higher than in 1930-1931 favoured by very low absolute humidity in October 1931 and rather low mean temperatures in February and March 1932.

Bombay Deccan.—*Forecast*—average to somewhat low incidence.

Result—incidence below average of recent years, but above that of 1930-1932 season with exceptionally low mean temperatures and saturation deficiencies from September 1931 to April 1932.

The plague forecast as a whole therefore has proved unusually accurate, especially when the climatic data subsequent to its issue are taken into account.

Forecast for 1933

(Worked out in London on 18th November, 1932, on climatic data to October received from India.)

General climatic conditions in 1932 to October.—India has once more been favoured with well-distributed monsoon rains in 1932, with moderate defect of 34 per cent. in Bihar, 32 per cent. in the Madras north coast area and the minor defect of 22 per cent. in the east United Provinces. The rainfall was in excess in the North-West Frontier Province and Sind. These conditions are unfavourable to widespread epidemics of cholera or smallpox in India as a whole, but the comparatively low hot-season temperatures and saturation deficiencies in the Deccan and eastern Central Provinces favour increased plague there. In view of the approximately normal climatic data for 1932 in most parts of India, the probable variations from the average of the three epidemic diseases dealt with may be stated briefly as follows.

Probable incidence of cholera in India during 1933

Assam.—1932 rains normal; recent incidence low. *Forecast*—about average incidence in 1933.

Bengal.—Monsoon slight defect of 12 per cent.; low recent incidence. *Forecast*—some increase in 1933 on the incidence of recent years.

Orissa.—June to September rains normal, but October rain low with deficiency in the north Madras districts to the south of Orissa. *Forecast*—increased incidence in 1933.

Bihar.—Monsoon rains to September 34 per cent. deficient, and also low in October; low cholera incidence in last two years. *Forecast*—increased incidence in 1933; this may be considerable if the winter rains are also short. Chota Nagpur will be liable to cholera infection from Bihar and Orissa.

United Provinces.—1932 rains 22 per cent. in defect in the east, but normal in the west; cholera incidence very low in 1932. *Forecast*—increased incidence in 1933, especially in the eastern districts.

Punjab.—1932 rains normal; recent cholera incidence low. *Forecast*—not likely to be epidemic, but some spread from the United Provinces probable.

North-West Frontier Province.—Monsoon in 1932 in excess; low recent prevalence. *Forecast*—not epidemic but may be some spread from the Punjab.

Sind.—1932 rains in considerable excess. *Forecast*—cholera incidence likely to be low.

Guzerat.—Normal rains. *Forecast*—no excess of cholera likely.

Bombay Deccan.—Good rains. *Forecast*—cholera prevalence likely to be average to low.

Central Provinces.—1932 monsoon in moderate excess; very low cholera in 1932. *Forecast*—

average to low prevalence, but probably above that of 1932.

South-East Madras.—Good October rains 1932; incidence low in 1932. *Forecast*—about the average unless the November to January rains are in defect.

North Madras Coast.—Low 1932 monsoon rains; low cholera in 1932. *Forecast*—increased prevalence in 1933, with incidence above the average.

Probable incidence of smallpox in India during 1933

The climatic data available to October 1932 only allow of forecasts of smallpox for north-west and central India for reasons explained in my memoir on the subject. *General.*—The favourable 1932 monsoon, with accompanying average monsoon absolute humidities in most of the areas dealt with, are unfavourable to any greatly increased prevalence of smallpox over the average in north-west and central India as a whole.

Punjab and North-West Frontier Province.—Monsoon absolute humidities from July to September about average, but October readings low. *Forecast*—about average prevalence, but probably some increase on the low 1932 incidence.

Central Provinces.—Monsoon and October absolute humidities normal; very low incidence in 1932. *Forecast*—average to low incidence in 1933.

Bombay and Madras Deccan.—1932 monsoon absolute humidities average in the north Deccan, but high in south Bombay and Madras Deccan. *Forecast*—low smallpox incidence in 1933, especially in the southern Deccan.

Probable incidence of plague in India during 1933

In general low rainfall with high temperatures and saturation deficiencies favour subsequent increased plague, and *vice versa*. The main variations from the normal of these factors and their bearing in plague incidence in the 1932-1933 plague season are as follows.

Bihar.—The hot weather and monsoon temperatures were in considerable excess, as were the saturation deficiencies from January to September 1932. *Forecast*—low plague incidence in the November 1932 to June 1933 plague season.

United Provinces.—Similar climatic conditions prevailed in 1932 in this province to those in Bihar, although to a slightly less degree. *Forecast*—low plague prevalence from November 1932 to June 1933.

Punjab.—Apart from increased saturation deficiency in the hot season the climatic conditions were normal in the Punjab in 1932. *Forecast*—average to low plague incidence in 1933.

THE DURATION OF THE LIFE OF THE EMBRYOS OF *WUCHERERIA BANCROFTI* IN THE HUMAN SYSTEM

By S. SUNDAR RAO, L.M.P.

Filariasis Research Worker, Calcutta School of Tropical Medicine

THE nocturnal periodicity of microfilaria in the peripheral blood, and the periodic manifestation of lymphangitis in persons infected with *Wuchereria bancrofti* are occurrences that have long been recognised, though of their cause little is known. That they must be intimately connected with the life-history of the parasite is obvious.

Several explanations have been offered for the nocturnal periodicity of the embryo. Fulleborn (1912) demonstrated that there was a positive attraction, chemical or otherwise, exerted by the Malpighian tubes of the mosquito upon the microfilariae of dogs. Yamada and Yamamoto (1916) considered that the condition could be ascribed to oxygen chemotaxis, and Suganuma (1921) that the most important cause of periodicity was the strong negative heliotropism of the embryo. The last author showed that microfilariae were positively chemotropic to carbon-dioxide, urea, uric acid and grape-sugar, negatively to ammonia and light. Lynch (1919) favoured a mechanical explanation because he noticed that in the collapsed lung of a dog infected with *Dirofilaria immitis* the embryos accumulated in enormous numbers. Yorke and Blacklock (1917) thought it depended primarily upon periodic variations in the arterial supply of larvae to the cutaneous vessels. Recently, Clayton Lane (1929) has contributed his views on the subject and has explained the periodicity by simultaneous cyclical parturition of the female worms and the daily death of the embryos.

A periodicity of recurrence of filarial lymphangitis in filarial subjects is also well

(Continued from previous column)

Central Provinces.—The climatic factors were mostly normal with deficient saturation deficiency favouring increased plague in one quarter. *Forecast*—average to high plague in the August 1931 to May 1933 season, most in the eastern districts bordering on the north Deccan.

Bombay Deccan.—The 1932 hot weather temperatures and saturation deficiencies were low and favourable to subsequent high plague incidence. *Forecast*—increased plague, especially in the north Deccan in the August 1932 to May 1933 season. (The last weekly returns show increased plague here.)

REFERENCE

Rogers, L. (1928). The Incidence and Spread of Cholera in India; Forecasting and Control of Epidemics. *Indian Med. Res. Memoirs*, No. 9.

known. Martinez Alvares (1920) reported a monthly periodicity observed in men and women alike, occurring during the dark phases of the moon, but never at the time of the full moon. A somewhat similar manifestation was observed by Acton and Rao (1930) on some cases of urticaria where the eruption appears periodically. They have suggested in this communication that the periodicity may have something to do with the habits and life-history of the parasite and that further studies may throw some valuable light on this problem.

As yet we know very little about the duration of life of the adult parasite or of its embryos in the human host. The duration of life of the embryos was thought to be a few hours by Myers (1881). Sonsino (1896) determined it as extending over a few days, and Bancroft (1901) as several months. The later work of Fulleborn (1912) on the filariæ of dogs and the transfusion of the blood with microfilariæ of *Dirofilaria repens* into healthy dogs showed that these embryos continue to be present in the system for a period of about three years.

Experiments for observing the duration of life of embryos of *Wuchereria bancrofti* have shown that under aseptic and cool conditions, i.e., in the neighbourhood of 4°C., they can be kept alive for about 4 to 6 weeks outside the body of the host. Our repeated observations made during the last few years have shown that the embryos can be kept alive for varying periods of time after being taken out of the host and that the adults manage to live only for a few hours under the same conditions. This will form the subject of a separate communication. Recently observations have been made which throw light on the probable duration of microfilariæ in the human system; these form the subject of this paper.

The following are the brief notes of the patients who were under observation.

Case I.—N. D., aged 48, Hindu male, a resident of Calcutta, admitted into the Carmichael Hospital for Tropical Diseases in March 1930 for a cyst on the left elbow, about an inch in diameter (figs. 1 and 2). The cyst was quite painless and had developed very slowly; it reached this size in a year's time. The cyst was tapped and 5 c.cm. of clear serous fluid was obtained from it. This fluid on microscopical examination showed innumerable live and active microfilariæ. The peripheral blood taken at midnight showed numerous microfilariæ. After the tapping, the cyst wall collapsed but the cyst had filled again within a few days. The cyst was excised under local anaesthesia. Five entire adult worms were found in the cyst. These findings have been recorded elsewhere (S. Rao, 1930). The peripheral blood was positive for microfilariæ till the time he left the hospital, an interval of five days. Blood examination for microfilariæ was carried out at intervals; it was found that the embryos disappeared completely between the second and the third month after the cyst was excised, and the patient has remained free from embryos since—the last examination of the blood for microfilariæ, made on 2nd September, 1932, showed no embryos.

Case II.—P. A., aged 27, Hindu male, a resident of Pabna (Bengal), admitted into the Carmichael Hospital

for Tropical Diseases on 4th July, 1932, for lymphangitis of the scrotum which ended in the formation of an abscess. Repeated examination of the blood showed no microfilariæ. Small cysts were detected, one on each arm, and on puncture with a hypodermic syringe 0.2

Fig. 1.—Photograph of case 1, showing the location of cyst on the left forearm.

Fig. 2.—Photograph of the cyst from case 1.

and 0.3 c.cm. of clear whitish fluid was drawn from each of them. The fluids from the cysts on microscopic examination showed a few microfilariæ in each. The cyst in the right axilla (fig. 3) was excised under local anaesthesia on 22nd July and several mature and immature worms, similarly actively moving inside the cyst, were collected. The second cyst on the left arm (fig. 3) was excised on 4th August and from this again

six adult worms were recovered. The peripheral blood, which was 'negative' till 4th August, showed microfilariae and table I shows the microfilariae count per 100 c.mm. of blood taken from the finger every 24 hours

Fig. 3.—Photograph of case 2, showing the location of the cysts on both the arms.

at midnight. From October 13th onwards the blood has remained entirely free from microfilariae, though examinations were continued for 37 days.

the blood is negative. So that, in both the cases, there is definite evidence of the cyst being the location of the adult worms and the sole source of embryos in the blood. As soon as the main colony of the adults and embryos was taken out by surgical operation, the few embryos which were able to get into the blood stream appear to have survived for about 70 days. At the end of this period they seem to have died out and disappeared completely. It seems therefore reasonable to draw the inference that the duration of life of the embryo coincides with the above period. It is evident that some of the embryos circulating in the peripheral blood at the time when the cysts were removed would be older than others, but the fact that at the end of about 70 days all have disappeared shows that the youngest of these have survived this period before finally dying out. The second case is still under observation so that it should be possible in the near future to confirm or refute the view about periodicity expressed above.

In this connection it may be pointed out that there is a certain element of uncertainty in relying on blood examination alone, because on certain occasions cases known to have large

14-8-32	2	28-8-32	1	11-9-32	0	25-9-32	0	9-10-32	0
15-8-32	3	29-8-32	0	12-9-32	0	26-9-32	0	10-10-32	0
16-8-32	0	30-8-32	0	13-9-32	0	27-9-32	0	11-10-32	0
17-8-32	1	31-8-32	0	14-9-32	0	28-9-32	0	12-10-32	2
18-8-32	1	1-9-32	0	15-9-32	0	29-9-32	1	13-10-32	0
19-8-32	2	2-9-32	2	16-9-32	0	30-9-32	2	14-10-32	0

There are also on our records several other cases where the appearance and disappearance of microfilariae in the blood show a regular periodicity. Since regular observations have not been made on these cases, they are not described here.

Discussion of observations

In the cases described above, the blood examination gave positive results for a certain period and then became negative. In the second case observations were carried out systematically, the embryos being present in the peripheral blood for a period of 70 days and then disappearing. The microfilariae appeared in the blood stream soon after the second cyst was cut out and then disappeared; up to the time of writing this communication

numbers of microfilariae in their blood may be completely negative. It is of course well known that the blood in cases of *Wuchereria bancrofti* infection has to be taken for examination at midnight to ensure getting definite proof of the infection. The cases cited above and numerous others in our records show that there may be great variations in the number of embryos found in the peripheral blood in different individuals at different times, though they may all be equally infected. Till the life-history of the parasite is thoroughly worked out it will not be possible to be positive about the duration of life of the embryos, for, even when experimenting with volunteers, it will be necessary first of all to know the age of the embryo before we can draw reliable conclusions.

THE TREATMENT OF CHRONIC INTES- TINAL AMOEBIASIS WITH THE ALKA- LOIDS OF *HOLARRHENA ANTIDYSEN- TERICA* (KURCHI)

By HUGH W. ACTON, C.I.E.

LIEUTENANT-COLONEL, I.M.S.

and

R. N. CHOPRA, M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

School of Tropical Medicine, Calcutta

CHOPRA and others (1927) have shown that the alkaloids of *Holarrhena antidysenterica* possess marked amœbicidal properties, and Ghosh and Ghosh (1928) have shown that the Indian species of *H. antidysenterica* contain, besides *conessine*, two other alkaloids which they named *kurchicine* and *kurchine*, respectively. Ghosh and Bose (1932) isolated these alkaloids in pure form and showed that the alkaloid, *kurchine*, is characterised by having a low melting point at 75°C., and that it is the most abundant alkaloid in the bark. Acton and Chopra (1929) pointed out that these alkaloids can be used in the treatment of amœbic dysentery in man. In contradistinction to emetine, they have no depressant, emetic or toxic properties, and their preparations can be

given by the mouth in fairly large doses without producing untoward effects. In acute amœbic dysentery intramuscular injections of two grains of the total alkaloids produced disappearance of *E. histolytica* from the stools as quickly as did emetine; they, however, produced severe irritation and pain at the site of injection, and all our efforts to produce compounds which would be less irritant were unsuccessful. These alkaloids, however, do not produce the other toxic effects of emetine, and, as soon as a non-irritant salt is prepared, their use in the treatment of acute intestinal amœbiasis will undoubtedly be extended.

For chronic intestinal amœbiasis, for reasons we have already discussed, it is preferable to give the alkaloids by the mouth, and we prepared and used a bismuthous iodide compound of the total alkaloids; this we called *kurchi bismuthous iodide*. This compound was originally prepared in 1928 on the same lines as emetine bismuth iodide. Its approximate composition is as follows:—total alkaloids, 27 per cent., bismuth, 22.85 per cent., and iodine, 50.15 per cent. Soon after these facts were published a number of firms started manufacturing the compound and put it on the market under various trade names. The latter fact is to be greatly regretted as the name *kurchi bismuthous iodide* is much more expressive and gives the practitioner a better idea as to what he is using than do the fancy names, which convey nothing and only create confusion. This compound can be administered in doses of 10 grains twice daily for ten to twenty days without any deleterious effects. Such doses cured a large number of chronic cases of intestinal amœbiasis which had proved resistant to treatment with emetine and other drugs. In a case of commencing liver abscess, however, Chopra and De (1930) found that injections of the alkaloids were ineffective.

For the last three years the authors have tried *kurchi bismuthous iodide* in a large number of cases, both inside and outside the hospital, with very satisfactory results. Complete records are available of a series of 77 cases treated in the Carmichael Hospital for Tropical Diseases and a summary of these is given in the appendix.

Before going into the details of these cases it is necessary to explain the somewhat discordant results obtained by different clinicians in the treatment of chronic intestinal amœbiasis with *kurchi bismuthous iodide*. We were ourselves considerably puzzled by contradictory findings for a long time. It must be stated here that, in the early trials with this compound, the isolation of the alkaloids and the preparation of the bismuthous iodide compound was carried out entirely in the Department of Chemistry of the School under the direct supervision of Dr. S. Ghosh, the Professor of Chemistry. With this preparation our results were uniformly good. The process of preparation was then given over to some of the local

(Continued from previous page)

In conclusion, the writer wishes to express his thanks to Lieut.-Colonel H. W. Acton, C.I.E., I.M.S., Director, Calcutta School of Tropical Medicine, for his active interest in the work and constant encouragement.

manufacturers and we started using their product in the treatment of our patients in the hospital. For a time all went well, but, after a particular preparation was started, practically all the patients under this treatment remained uncured. On investigation it was discovered that the process of manufacture described by us had been modified, and in order to facilitate the extraction of the alkaloids, hot alcohol had been used instead of the cold as originally recommended. This had the effect of changing the alkaloids, and possibly radical changes were produced in the one with a low melting point which forms the chief constituent. This was rectified and our results considerably improved for a time. In the meantime the demand for kurchi bismuthous iodide increased enormously, and after a while we again started getting failures in almost all our patients treated with this compound. On further investigation and careful survey of all the facts we came to the conclusion that this time the failures were to be attributed to the fact that the supply of good fully-matured bark could not keep pace with the large demand and that consequently large quantities of immature, improperly-collected and imperfectly-dried bark were coming into the market. Such bark was being employed for the extraction of the alkaloids used in the preparation of kurchi bismuthous iodide. To confirm this view we obtained matured and properly-collected bark from Assam, and prepared the bismuthous iodide compound from this material in our laboratory. Of a series of 13 cases treated with this preparation 10 (76.92 per cent.) were cured and 3 (23.08 per cent.) failed. The discordant results, in our opinion so far as kurchi bismuthous iodide is concerned, are due to :—

1. Some fault in the procedure of extraction of the alkaloids from the bark or preparation of the compound, e.g., use of hot alcohol instead of cold.

2. The bark from which the alkaloids are extracted not being mature, being improperly collected, or being imperfectly dried.

Besides these, there are two other factors which have an important bearing on the curative effects produced by this compound. Firstly, it is well known that in some of the chronic cases of amoebiasis there is mixed infection with bacillary dysentery also. The bacterial cultures from the stools of such patients show various non-lactose-fermenting organisms which complicate matters and delay cure. The isolation of these organisms is often a difficult matter and they are missed unless repeated examinations of stools are made by an expert bacteriologist. In such cases, unless a course of vaccines is given as a preliminary to treatment with the bismuthous iodide compound, the chances of cure are not so favourable. In some of our cases where such a state of affairs existed, a course of autogenous vaccines, preceding the treatment with kurchi bismuthous

iodide, often produced cures where the drug alone failed. The patients with mixed infections are much more resistant to treatment than simple cases.

Secondly, the reaction of the gut contents is often strongly acid in chronic intestinal amoebiasis and the action of these alkaloids is considerably weakened on this account. By administering kurchi bismuthous iodide with large doses of alkalies the chances of cure are greatly enhanced. The routine treatment followed in most of our patients was to give a mixture consisting of one drachm of sodium bicarbonate and 40 grains of sodium citrate half an hour before each dose of the bismuthous iodide.

The compound itself was given in doses of 10 grains administered twice daily for ten consecutive days. One such course sufficed to produce a cure in the majority of cases of chronic intestinal amoebiasis and *E. histolytica*, both vegetative and cystic forms, disappeared from the stools. The patient is kept on ordinary diet, no strict dieting being necessary except when the relapse is very acute. Sometimes, a second course is necessary. As these alkaloids are rapidly excreted from the body, and, unlike emetine, do not produce any cumulative toxic effects, the second course can be given immediately following the first course. Often it is not necessary to give a complete second course of ten days, only half a course, i.e., administration of the drug for fifteen days altogether, sufficing. Our experience is that in simple cases where there is no infection with bacillary dysentery, a ten-days' course cures a large number of cases, but when a mixed infection is present a course of 15 to 20 days is necessary. Even after a course of 20 days a number of cases prove resistant to treatment. Some of these yield to treatment with emetine bismuthous iodide, others do not. For this latter group we do not recommend another course of kurchi bismuthous iodide, but prolonged treatment with standardised extract of kurchi (containing half a grain of the total alkaloids in one drachm) often produces satisfactory results. One to two drachms of the extract are given twice daily for three months or even longer if necessary. Such doses do not produce any toxic effects and cure about 50 per cent. of the obstinate and persistent cases.

The extract may be given by itself or may be combined with *Plantago ovata* (Isabgul). The two drugs can be given concurrently, or alternately for ten days at a time, *Plantago ovata* being given in doses of 1 to 2 heaped tablespoonfuls, once or twice daily. Chopra (1930) showed that the action of the seeds is mechanical, and due to the large quantities of the mucilage which is contained in the superficial layers of the seeds. This covers the ulcers and protects them from the irritating contents of the intestines, solids, fluids and gases, in this way enabling the lesions to heal

quickly. Further, the gel formed from the seeds inhibits the growth of intestinal bacteria and adsorbs the toxins formed by them, thus preventing them from being absorbed into the system.

We have not met with any serious toxic or cumulative effects from the use of either the extract, the alkaloids, or kurchi bismuthous iodide, in the doses stated above. As much as six grains of the alkaloids were given by the mouth for 10 to 20 consecutive days without producing untoward effects. Rarely, flushing of the face and extremities, buzzing in the head and giddiness were produced, especially in the European patients, but these passed off when the dose was reduced. The taste of the alkaloids is very bitter and some patients object to it. This can be avoided by giving the compound in capsules or in tablet form.

The criterion of cure applied by us in this series was five or more negative examinations of the stools on different days after the cessation of all treatment. It is fully realised that it cannot be claimed from this that all such cases were really cured, but it is the best criterion that can be employed and from experience we know that 5 negative examinations indicate a favourable prognosis. The difficulty of keeping the patient in the hospital, when once the acute symptoms are relieved, is very great, so for practical purposes we had to accept this criterion. Whenever possible more examinations were made and in some as many as 10 or 12 stools were examined. If either vegetative or the encysted forms of *E. histolytica* were found in the stools after the cessation of treatment it is clear that the infection was not eradicated. Such cases mean entire failure of treatment. The 'indeterminate' cases were those in which less than five stools could be examined after cessation of all the treatment owing to the patient leaving the hospital earlier. It is impossible to say whether such cases will or will not relapse.

The appendix is self explanatory. A perusal of it will show that in all 78 cases of intestinal amœbiasis were treated with kurchi bismuthous iodide, in the Carmichael Hospital for Tropical Diseases during the last three years. Many of these patients gave a history of dysentery lasting for many years, and had cystic forms of *E. histolytica* and Charcot-Leyden crystals in their stools. In this series it will be observed that with the criterion of cure laid down above, 57 patients or 73 per cent. were cured, 3 or 3.84 per cent. were indeterminate, and 18 or 23.1 per cent. failed to be cured. The proportion of probable cures to failures in this series is 3.16:1, as compared with 1:3.5 obtained by Knowles (1928) with emetine bismuthous iodide in similar chronic cases. A further study of the appendix will show that out of 42 patients who had cystic forms of *E. histolytica* in the stools, 31 were cured and 11 failed, the ratio of probable cures to failures here being 2.8:1.

Among the failures, it is interesting to note that 11 had only cystic forms and seven vegetative forms of *E. histolytica* before treatment; some of the former (nos. 42, 48, 64, and 78) subsequently received emetine treatment and still remained uncured. It was further observed that, in the patients with vegetative forms of *E. histolytica*, the vegetative form was often converted into the cystic form after unsuccessful treatment with the bismuthous iodide compound. The probable explanation is that these alkaloids make the gut wall an unfavourable abode for these protozoa which then develop into the cystic stage. This fact lends an indirect support to the view that the alkaloids of *H. antidyenterica* are toxic to *E. histolytica*.

The last five cases in the series were very resistant cases of mixed infection and were treated both with vaccines and kurchi bismuthous iodide. Three out of five cases were cured and two failed.

Summary and conclusions

1. The alkaloids of *H. antidyenterica* are powerful curative agents in intestinal amœbiasis. In acute amœbic dysentery intramuscular injections of 2 grains daily of the hydrochloride produce a cure as rapidly as emetine, but they are very painful.

2. The bismuthous iodide compound of the total alkaloids is an effective remedy against chronic intestinal amœbiasis. The proportion of probable cures to failures in a series of 78 cases was 3.16:1, which compares favourably with Knowles series with emetine bismuth iodide, in which this ratio was 1:3.5.

3. The bismuthous iodide should be administered in doses of 10 grains twice daily preceded half an hour by a mixture containing one drachm of sodium bicarbonate and 40 grains of sodium citrate. No strict dietary measures are necessary unless the relapse is of a very acute nature.

4. In simple cases, where there is no mixed infection with bacillary dysentery, a course of ten days' duration cures a large number of patients. When a mixed infection exists a course of 15 to 20 days may be necessary. A second course is not desirable.

5. In obstinate and persistent cases resisting treatment, a prolonged course (3 months or more) of standardised extract of kurchi 1 to 2 drachms twice daily, with or without *Plantago ovata* (Isabgul) is often effective.

6. When mixed infections exist a course of autogenous vaccines should precede the treatment with the kurchi bismuthous iodide compound.

We are very grateful to Dr. B. Sen, B.Sc., M.B., for his help in collecting and analysing the case notes.

A STUDY ON THE PREPARATION OF AN EFFICIENT EXTRACT OF KURCHI (*HOLARRHENA ANTIDYSENTERICA*)

By ARABINDA BHUSHAN GHOSH

Assistant Analyst, Bengal Excise Department, Bengal
Public Health Laboratory, Calcutta

THE bark of kurchi (*Holarrhena antidysenterica*) has been spoken of since prehistoric days as an efficient remedy for dysentery. It has been mentioned by Charaka and others in the books of oriental medical science. Lately, the drug has attracted the attention of modern scientists and pharmacologists, so much so that articles regarding the determination of its active principles and its chemistry have been published by no less than a dozen workers within the course of a few years. The therapeutic value of the drug has been found to be due mainly to its contained alkaloids whose actions are as potent as those of emetine, without producing the toxic effect of the latter.

The researches of Acton and Chopra have definitely established that the alkaloids in kurchi have a similar amœbicidal effect to that of emetine. Again, some other workers (Henry and Brown, 1924) hold that conessine, the principal alkaloid of kurchi, alone, like emetine, has less protozoocidal effect *in vitro* than when it is administered in a dilute acid or alkaline medium. They are also of opinion that the efficacy of these and other alkaloids of similar drugs is enhanced when they are administered along with the associated tannins contained in the drugs. They are, however, silent about the effect of the resinous matter in them. This observation of the greater efficacy of the alkaloid when administered with other substances reminds us at once of the applications of many drugs as a whole in our Ayurvedic system. Unfortunately, with the exception of the work of Henry and Brown, which only touches on the subject, there has been to date no scientific investigation on these lines.

The clinical study of the extracts of kurchi, both watery and alcoholic, by A. R. Majumdar (1930) reveals two facts: (1) watery decoctions of kurchi are worthless clinically, and (2) a standardised extract containing a reasonable amount of alkaloids is necessary to get any result in cases of amœbic dysentery. According to him a patient with frequent stools requires 3 to 4 grains of total alkaloids daily. Keeping this in view, in collaboration with the Bengal Chemical and Pharmaceutical Works, he has worked out a process for preparing such an extract containing 1 per cent. $\frac{w}{v}$ of total alkaloids of kurchi. But he has not given the method of preparing this extract in his article. Although Acton and Chopra have reported favourably upon the amœbicidal effect of kurchi-bismuth-iodide, the price of this salt is rather high. Alcoholic extracts of kurchi are both cheaper than any other preparations, and

are handy to administer. But any extract of kurchi will be worthless unless it is standardised.

Having been associated with the analytical side of the medicinal preparations, official, non-official and indigenous, in the Bengal Excise Laboratory under the Public Health Department, the writer has had ample opportunity of testing alcoholic extracts of kurchi produced by the local manufacturers. Real difficulty has been felt in the laboratory when considering the permissibility of granting a licence to manufacture an extract of the same drug at different alcoholic strengths. The necessity of standardising the useful indigenous drugs is thus keenly felt in order to force the manufacturers to put on the market uniform standard preparations. In the absence of standard methods of preparing tinctures and extracts from indigenous drugs, it is very difficult to say which preparation of these drugs is good and which is bad. Taking the concrete example of alcoholic kurchi extract, it has been found that various bazar preparations of this drug are quite different from each other. Some have a low alkaloidal and high tannin and resinous content, while others have a high alkaloidal and low resinous content. The standardisation is thus obviously very necessary. According to Dr. Majumdar (1930), kurchi is so efficacious in cases of amœbic dysentery that it is expected that it will in the near future be included in the British Pharmacopœia. To quote him, 'What preparation will give the maximum effect with the minimum cost is still an open question'; the fact is at once clear that an investigation is necessary into the nature of alcoholic extracts of kurchi (which in the writer's opinion are undoubtedly the cheapest of all preparations) in order to get an idea which of the alcoholic preparations will really be suitable from all points of view. Bearing these points in mind the writer has carried out some experiments in the provincial excise laboratory under the Bengal Public Health Department, the result of which is expected to throw some light on this yet unsolved problem.

EXPERIMENTS

Experiment 1.—Total alkaloid—A sample of kurchi bark supplied through the courtesy of the chemist in charge of Bathgate & Co.'s bonded laboratory was assayed for total alkaloids. The bark was finely powdered and bottled. Ten grammes of this powdered bark were macerated with 6 grammes of slaked lime with a little water and mixed. The whole was then refluxed with benzene and amyl alcohol mixture for 30 minutes and filtered. The residue was further refluxed with a fresh portion of benzene mixture and filtered, and the residue thoroughly washed with the same mixture repeatedly till free from alkaloid. An aliquot portion representing 5 grammes of the bark was exhausted with dilute hydrochloric acid till all the alkaloid was taken up. The alkaloid was

The disease appears to be equally common in men and women in South India. Table II shows the distribution as regards sex among the admissions to the Rayapuram Hospital, for five years. The reputed higher incidence in women has not been met with here.

TABLE II

Sex distribution of granuloma inguinale

Sex	Number of cases	Percentage
Males	27	50.9
Females	26	49.1
TOTAL	53	..

The age distribution of the disease corresponds with the period of maximum sexual activity. The disease is rare in childhood and old age. In two of the cases that occurred in young boys of fifteen the granuloma was around the anus and there was a definite history of sodomy.

The site of the early lesion

Granuloma inguinale has been described as most often met with in the groin. It has often been described on the external aspect of the labia in women. Primary involvement of the mucous membrane of the glans penis has been held to be rare and also a primary involvement of the vaginal wall or cervix. Its venereal origin has been questioned. The involvement of the genitalia has been held to be result of spread of infection from the groin. However, very often a careful analysis of the history will reveal the occurrence of a small sore on the skin or mucosa of the penis, that often heals, and is followed by the development of the granuloma in some part of the genitalia or groin. Very often the history is that of a bubo following a sore. This may have opened of itself or been opened by the surgeon, the granuloma developing at the site of the opening. In other cases the sore on the prepuce persists and gradually passes on into a large granulomatous

ulcer, that involves the shaft of the penis and spreads to the scrotum. Another history that is often obtained is that of a sore that heals and breaks down again, or has been removed by circumcision, the granuloma developing at the line of incision.

TABLE IV

Site of the primary lesion in granuloma inguinale in men

A similar analysis could not be made in women since the history was vague.

Thus it becomes apparent that genital infection is possible and does occur in most of the cases in South India. Other modes of infection are possible, since the disease is auto-inoculable. It has been held that prolonged contact is necessary for infection. De Vogel however puts down the incubation period as two weeks. In Guldberg's case the granuloma developed from a bubo which occurred 14 days after as small sore on the penis. While primary lesions are difficult to trace in women, a careful inquiry into the history will often reveal that there has been a sore on the vaginal wall or labia some time before the occurrence of the granuloma. The condition may have been mistaken for a chancre or a soft sore. Extensive ulceration of the vaginal wall may be met with, but this is often late in the disease. Ulceration of the skin round the anus or of the perineum may occur as the very first lesion. Rarely the lower abdominal wall may be the site. If we take into account the analogy with a disease of undoubted venereal origin like syphilis, and the relative frequency of extra-genital chancres, a primary extra-genital lesion in granuloma is just as common. Figure 1 illustrates a case where a granuloma on the lips followed disease on the genitalia. In another case shown to me, an ulcer developed on the cheek following a granuloma on the genitalia. In Donovan's (1905) classical case where the parasite was first described, the granuloma was on the lip following disease of the genitalia. Fox records numerous extra-genital sites such as the nose, cheek, lips, neck, larynx, pharynx, back of hand and thigh. In Thierfelder's (1925) case the

process extended from the external into the middle ear.

The morphology of the lesion.—The earliest lesions that have been noticed, what may be called the primary lesion in granuloma inguinale, are on some part of the genitals. It is about the size of a pea or even smaller. Over this the skin becomes boggy and soft even at the commencement, indicating that the primary infection is through some breach of the surface. This primary sore, as I have called it, is not often diagnosed as granuloma, and very often heals. This early nodule is pink and vascular. Its surface is covered by a thin serous discharge.

Fig. 1.—Inguinal granuloma. Lesion on the lip. There was extensive disease on the genitalia.

Induration is not so marked as in a chancre and the lesion might be mistaken for a soft sore, but the reaction is milder and there is not that angry looking base and raw inflamed edges that are met with in a soft sore. The fully developed granuloma, as distinct from a soft sore, is much more distinctive, in that the surface of the ulcer is raised up above the skin as a nodule with a central mass of granulations. Gradually the inflammatory process spreads and forms an extensive ulcer which often presents the appearance of healing. In women the story is that of a sore on the labia that heals, but the cicatrix breaks down again and forms an intractable ulcer that is extremely chronic. Side by side with lesions on the genitalia, lesions develop on the groin, at the crural angles, and on the skin of the perineum. In any case the striking feature of the ulcer is the new growth of tissue that projects above the surface. This consists of a mass of coarse pink granulations or even nodules that projects above the surface, and shows at the edges a dull bluish appearance from growth of epithelium. The mass is

soft and very vascular, the granulations varying in size from a pin's head to coarse nodules of the size of a pea or bean. The edges are always raised, crenated and wavy, gradually extending in places while other areas show definite healing. The condition is extremely chronic and indolent, the ulcer continuing to spread for months or even years. The cicatrization may be on one side or more irregular, the cicatrix often breaking down in the centre discharging a thin serous fluid. In many cases the infection may spread to contiguous surfaces, probably by auto-inoculation; but even apart from this, fresh foci in the shape of small nodules quite commonly may be met with in the neighbouring skin. In other cases, these nodules are small abscesses containing granular purulent material. Sometimes tumour-like nodules may communicate with cavities and may continue to discharge thin sero-purulent material, and the condition may clinically resemble mycetoma. On the other hand, extensive scabbing may be present at the edge of the ulcer, particularly when secondary infections with pyogenic cocci are present.

The process spreads in an annular fashion especially in the groin. It may encircle the genitalia extending across the mons and behind to the perineum. On the genitalia extension may occur in any direction, but more commonly the folds of integument such as the peno-scrotal angle, or the outer or inner edge of the labia may be affected. Dense cicatrization may occur with healing, giving rise to extreme deformity, hence the name 'sclerosing granuloma'. In women the urethral canal may be involved and the meatus may be converted into a wide irregular opening with thick sclerosed edges (see figure 2). Sometimes large polypoid masses

Fig. 2.—Cicatrization following granuloma inguinale, with involvement of the urethral canal.

may project from the urethral canal and the condition may be mistaken for caruncle. Involvement of the cervix is not usual. A common feature met with in women, and due to obstruction of the deep lymphatics of the skin of the genitalia, is a solid oedema of the vulva with a thickening of the skin. In other cases the obstruction may be more irregular, and

nodular polypoid grape-like masses of hypertrophied skin may project from the labia with cicatrising ulcers on the outer side, a condition that may resemble elephantiasis (see figure 3). A true non-filarial elephantiasis of the

Fig. 3.—Polypoid masses projecting from the vulva; pseudo-elephantoid condition due to granuloma inguinale.

vulva may occur and the mass may be so large as to require removal. Spread may occur along the inner side of the thigh as low down as the knee.

As has already been mentioned, extra-genital infection with granuloma is rare, but occasionally cases may be met with in the axilla and the lower abdominal wall, and they may be mistaken for lupus. Ulceration round the anus is quite common without lesions on the genitalia. This may be followed by sclerosis with stricture of the anal canal. These cases are much more resistant to treatment, they frequently heal up and break down again. Other extra-genital sites of infection, such as the lips and cheeks, are mere associated lesions.

Enlargement of the lymphatic glands is not well defined or distinctive when the lesion is well developed, though it occurs to a slight extent in about 40 per cent. of cases. It is,

however, premature to decide whether a lymphadenitis occurs in all cases during what I have called the primary stage of the disease. That such lymphadenitis does occur in some of the cases is evident from the history of bubo that is often met with. In some cases even late in the disease, an acute septic lymphadenitis does occur followed by suppuration.

TABLE VI

Enlargement of the lymphatic glands of the groin in 39 cases of granuloma inguinale

Type of enlargement	Number of cases	Percentage
Well-defined enlargement ..	9	23.1
Slight enlargement ..	7	18.0

Visceralisation has been described by Thierfelder and a case of abscess of the liver has been recorded. So far no such cases have been met with in Madras, though it is difficult to say how far the internal organs are affected in those cases which terminate in chronic cachexia. Chronic cystitis may occasionally be met with in women. In cases with extensive disease of the perineum the process seems to spread up to and involve the rectum and surrounding tissues, and very often death occurs from cachexia with a low type of fever. Spontaneous cure may be met with rarely, but occasionally cases occur where a cure has been effected by the application of caustics. Syphilis may co-exist and complicate the clinical picture, but the serum reactions are distinctive. A well-defined positive Wassermann reaction is never met with in granuloma inguinale unless syphilis co-exists.

The histology of the lesion

A study of the early nodules that are met with, shows two distinctive features. There is in the main a desquamation of the superficial layers of the epidermis so that the keratinised layers are lost. Together with this there is a cell infiltration of the corium in the papillae just below the germinal layer. The deeper layers of the epidermis show a tendency to become spread out owing to a swelling of the intercellular material. Over the ulcerated area these layers are cast off, but proliferation occurs in the neighbourhood, so that the normal papillary folds are exaggerated and down growths of epithelium are prominent (see figure 4). The denuded area presents the appearance of acute inflammation. Emigration of leucocytes forms a prominent feature, but exudation and fibrin formation are scanty. The type of cell reaction on the surface is mostly polymorphonuclear, but mononuclears are present in numbers. Just below the surface is granulation tissue containing numerous endothelial cells and fibroblasts arranged around embryonic

capillary loops. Superficial necrosis of tissue is not well marked. In the swollen endothelium of the newly-formed solid capillary buds, and in the mononuclear wandering cells, clumps of coccoid and cocco-bacillary bodies may occasionally be made out.

Fig. 4.—Inguinal granuloma ($\times 125$ approximately) showing an early nodule under the epidermis. Note the atrophy of the epithelium over the nodule and the proliferation in the neighbourhood.

Fig. 5.—Inguinal granuloma ($\times 750$ approximately) showing the embryonic capillary buds surrounded by lymphocytes and proliferating endothelium.

While this is the type of reaction that is present on the surface, the deeper layers show evidences of chronic inflammation in the

well-developed granuloma. Polymorphonuclear leucocytes are not so numerous, but accumulations of lymphocytes and plasma cells are marked, especially round the small blood vessels, a feature that is quite like the reaction that is met with in syphilis (see figure 5). Endarteritis obliterans, however, is not a feature in this series of cases. Proliferation of fibroblasts is quite well marked in the deeper layers. In old cases, there are dense strands of fibrous tissue with here and there collections of plasma cells and lymphocytes in the crevices of tissue and around small capillaries. Giant-cell formation is not met with and caseation necrosis does not occur. The epithelium in the neighbourhood shows a loss of the keratinised layers. The whole histological picture is distinctive and resembles to some extent the reaction in the primary sore of syphilis. Manson-Bahr (1929) notices a resemblance to the morphology of rhinoscleroma, but this is more apparent than real, since the nodules of rhinoscleroma seldom ulcerate and the histologic reaction is sufficiently distinctive, the characteristic feature being the presence of the large cells of Mikulicz—the rhinoscleroma cells—which are not met with in granuloma.

Discussion

The primary lesion in granuloma has been overlooked. The infection has been believed to be through some breach of surface, but the history of a definite primary sore, that is often met with, has not been emphasised. The reputed common incidence on the groin has been looked upon as indicating a non-venereal origin, since definite venereal lesions would mostly be on the genitalia. The name inguinal granuloma itself lays stress on the occurrence of lesions in the groin. The condition has been even looked upon as a primary disease of the skin of the groin, occurring by inoculation of abraded areas in the tropics, where lesions caused by fungi are quite common in and about the inguinal region. Sexual contact, according to this view, is only one of the modes of infection. The difficulty in experimental reproduction of the disease, its sparse incidence and race distribution have been put forward as against a venereal origin.

The present study emphasises that the main incidence of the disease is on the genitalia and not on the groin. The condition is met with at the period of life associated with the greatest sexual activity. The primary lesion is a sore that most often heals over, and is most commonly found in the genitalia. Whether this primary lesion is a separate factor and merely serves as a means for the entrance of the infective agent of the granuloma is yet uncertain; but the tendency to healing side by side with ulceration and the primary sore which often heals and breaks down again are features of

granulomata. That the infection is one that does not readily 'catch' is evident. The curious incidence of granuloma on a circumcision wound and at the side of a bubo that has been opened, indicates that the infective agent is present in the tissues in and about the genitalia. This also points to the existence of a previous stage, when the virus gains an entrance into the tissues. With regard to the mode of infection there are thus only two possibilities. The primary sore may be caused by one phase of the infective agent which lies dormant or undergoes multiplication in the tissues; or it may be that the granuloma is of the nature of a secondary infection, the primary sore being of different origin. The existence of lymphadenitis has been denied; but that it does occur in a fair proportion of cases is evident from table VI. That a lymphatic involvement may occur in the early stage of the disease is probable, from the frequency of the disease in the groin following on lesions on the genitalia.

Thus a study of the site of the lesion in granuloma inguinale and its mode of commencement indicate that the condition is most often met with in the genitalia, and that it is of venereal origin.

The term venereal granuloma would thus be more suitable, as indicating the real nature of the condition.

Acknowledgments

Some of the cases cited above were under the care of Mr. R. V. Rajam, M.S., M.R.C.P.E., Venereal Surgeon, General Hospital, Madras, and the others were under the care of Mr. C. R. Krishnasamy, M.B., C.M., Honorary Venereal Surgeon, Government Rayapuram Hospital, Madras. The writer has great pleasure in acknowledging their kindness in allowing him to examine some of their cases and study their records. He is also greatly indebted to Dr. Stephanos, the lady doctor in charge of the women's section of the out-patient department of the Rayapuram Hospital, for her kind co-operation in the study of some of the cases. To Dr. A. S. Annamalai and Dr. S. Krishnasamy of the Pathology Department of this hospital the writer is equally indebted for assistance in compiling the records of cases cited.

RABIES IN THE MONGOOSE

FURTHER OBSERVATIONS

By S. D. S. GREVAL, B.Sc. (Punjab), M.D., Ch.B.,
D.P.H. (Liverpool)
MAJOR, I.M.S.

Pasteur Institute, Kasauli

I. Reports from records

SINCE the last communication was sent (Grevall, 1932) information has been received about seven more cases of mongoose bite, one at Lahore, another at Lucknow, and five at Kasauli. The following Kasauli cases are worth recording:—

1. Case No. 4791 of 1932

J. S., aged 'about' 50 (more probably 60), male, of S. J., near Chhajli, near Sanam, Patiala State. Bitten on 1st August, 1932. Came for treatment on 3rd August, 1932. Finished treatment on 17th August, 1932. He stated:—

'I was sitting outside my house when a mongoose rushed at me and caught hold of my finger tip. A few boys of the village came running after it saying that it was mad and had bitten a dog and a grown-up calf in the village. The mongoose, however, escaped into an enclosure where farmers stack dry sticks and fuel of similar nature.

In detaching the mongoose I had to roll it over and discovered that it was a male. It was seen again the same evening and is still at large. The women and children are avoiding that part of the village.

The village is a small one and consists of about 100 houses surrounded by fields.

The wound bled profusely for some time after the bite.

At Borah, in Nabha State, at a distance of some 17 to 18 kos from my village, two years ago, a man was bitten by a mongoose. He did not undergo any anti-rabic treatment and died, 10 to 15 days after the bite, from hydrophobia. He had to be chained up for two days before he died.

Last year two patients from my village were treated at Kasauli for jackal bite.'

(Translated from Punjabi by S. D. S. G.)

2. Case No. 5001 of 1932

P., aged 7½, male, of J. G., district Kangra. Bitten 10th August, 1932. Brought for treatment on 14th August, 1932. Finished treatment on 27th August, 1932. His father stated:—

'The boy was playing in a room in the house when a mongoose came in, bit the boy on the face without provocation and ran away. Next day the mongoose bit another boy outside his house about a furlong from our house. It was then chased and killed.

Besides the two boys the animal had attacked two men who avoided being bitten.

The animal was uttering the sound of *khen khen khen* and was not afraid of even a crowd.

I have known mongooses to be mad before. It is a common knowledge in my part of the country that cattle bitten by them die. I have brought the boy for treatment because of the bite on the face. For serious bites I have no faith in indigenous medicines for rabies. The other boy was bitten on the hand.* He is being treated in the village by indigenous medicines.

The wounds were cauterised next day. A swelling on the face had been noticed the previous evening.'

(Translated from Hindi by S. D. S. G.)

* The seriousness of a bite on the fingers was pointed out to the patient.

3. Case No. 5077 of 1932

H. R., aged 22, a Patwari at IX, tahsil K. P., district Sri Ganga Nagar, canal area. Bitten 4th August, 1932. Came for treatment on 17th August, 1932. Finished treatment on 30th August, 1932. He stated:—

'I was sleeping, in the rest house, on a *charpai*, when I heard the sound of *cur cur cur*. A little later a mongoose caught hold of one of my fingers. I jerked the animal off and in doing so banged it against the edge of the *charpai*. I also called out for help and obtained a stick. I had hardly pointed the stick at the animal when it jumped at me but caught hold of the edge of the *charpai* instead. It also attacked two more men who had come in but did not succeed in inflicting a bite. One of these men hit it with a heavy stick and threw it out of the room where it died in a convulsion.

The animal was a female but had no litter teats (small and dry).

In the same bungalow, the previous night, another man was also bitten by what he had thought to be a snake. His wounds were cauterised.

My father is a *hakim*. He consulted the *Tib-i-Akbar* and found that mongooses suffer from rabies like dogs. He gave me onion water to drink and also onion pulp in food. I also attended a hospital at K. but was advised to go to Ganga Nagar. The doctor at Ganga Nagar wrote to Kasauli with the result that I am here.'

(Translated from Urdu by S. D. S. G.)

4. Case No. 6313 of 1932

B. S., aged 6, male, of L., district Karnal. Bitten 27th October, 1932. Brought for treatment on 29th October, 1932. Still under treatment (on 10th November, 1932). His father states:—

'The boy was seated in an open-air class of a village school when a mongoose rushed in amongst the class and bit him on the lip. The boy beat off the animal with his cap. It then attacked another boy (the next case). The animal was then killed. I have not heard of mongooses attacking unprovoked before.

The village consists of about 50 houses. The school has a hedge round it.'

5. Case No. 6341 of 1932

J., aged 9, male, of L., district Karnal. Bitten on 27th October, 1932. Brought for treatment on 29th October, 1932. Still under treatment (on 10th November, 1932). This is the other boy referred to above. He was also bitten on the face.

These cases together with the cases given in the previous communication total eight bitten by seven mongooses in seven different localities. Adding to them the two cases from Lahore and Lucknow and the mongoose proved rabid microscopically (previous communication) there have been reported ten cases of mongoose bites and ten biting mongooses, in ten different localities, during the last seven months.

Further information has also been received about the girl bitten badly, on 3rd May, 1932, by a rabid mongoose and not treated by modern methods (items 1 and 2 of the last communication) and also about the position of true rabies in South Africa where its existence appears to have been doubted.

Copy of a letter from G. S. V. A., dated B., district Jullundur, 13th October, 1932. Receipt No. 9902 of 1932.

'Dear Sir,—The girl bitten by the mongoose is quite all right. There is no complaint of any kind. This statement is submitted as an information.

—G. S. V. A.'

(Translated by S. D. S. G. from Urdu.)

Copy of a letter from the South African Institute for Medical Research, Hospital Street, Johannesburg, dated 12th July, 1932.

'Dear Sir,—The existence of rabies in South Africa has recently been established.

In this connection we are desirous of carrying out experimental work to ascertain whether local strains of the virus are similar to those of overseas origin. For this purpose we should be very grateful if you would be good enough to let us have small portions of glycerinated brain or cord tissue representing—(a) street virus, (b) fixed virus, obtained from cases of rabies in your district.

Details of the origin, virulence, etc., of the specimens as well as any information relative to differences in strain of rabies virus that you have encountered would be very highly appreciated.—I remain,

Yours faithfully,
S. L.,
Director.'

II. Comments and speculation

In all the five cases described above we are, evidently, dealing with rabid mongooses. The localities are instances of small human habitations surrounded by vegetation thick enough to offer an habitat to a wild carnivore, the mongoose. A direct introduction of rabies by the wild carnivore without the intermediation of the domestic carnivore, the dog, is being observed. The fact seems to be fairly well known to farmers from observations on man and cattle.

The question arises whether the virus in the wild carnivores is more virulent or less so than in the dog. The girl 'bitten badly' by a rabid mongoose (proved microscopically) and not treated by modern methods has not died. On the other hand a man is said to have died in 10 to 15 days after a mongoose bite. Similar differences in the infectivity of rabid dogs are well known. The rabid mongooses appear to have been more active and energetic than rabid dogs usually are. Do the wild carnivores stand the disease better than the dogs and sometimes get over it? Is there a definite chronic state of the disease to be found amongst them? Both these occurrences have been recorded as rarities in rabbits infected with fixed virus under experimental conditions (Remlinger, 1919) and in dogs infected with street virus under natural conditions (Marie, 1927). Are these occurrences common amongst the wild carnivores which live under more natural conditions than the domestic carnivores? The *phonhin* (or female jackal with a litter) believed by the farmers in this part of the Punjab to be the primary vector of rabies is heard in the villages for weeks together at nights. Biologically it is not in the best interests of a parasite (which presumably the virus of rabies is) to be always lethal in infection, as by being so it is likely to exhaust its nidus and thus exterminate itself.

The letter from South Africa defines the position of rabies in that country. The disease appears to be true rabies in spite of the 'fact

that it has been confined to the wild carnivores (of the family Viveridæ) ' (McKendrick, 1931).

Does the disease, then, smoulder in the forests and flare up in inhabited areas because of the greater liability and susceptibility of the dog when compared to the wild carnivores? Does the apparent stamping out of the disease mean an extinguishing of the flaring only and not of the smouldering? The facts recorded in this and the previous communication appear to favour this view.

Summary

1. Five cases of mongoose bite treated at Kasauli have been described. Adding to them the cases previously described, the cases treated at the centres served from Kasauli and a mongoose brain examined at Kasauli, there have been reported ten cases of mongoose bite and ten biting mongooses, in ten different localities, during the last seven months.

2. A note is made of the fact that the existence of rabies in South Africa has recently been established in spite of the fact that the dog is not the usual vector.

3. The suggestion made in the previous communication that rabies may be essentially a disease of jungles is repeated. A further suggestion is made that the disease may not be always fatal in jungles, amongst the wild carnivores.

AN EASY METHOD FOR ESTIMATING THE PROTEIN CONTENT OF MILK

By B. B. BRAHMACHARI, D.P.H.

Director of Public Health Laboratory, Bengal

IN the routine analyses of milk under the Food Adulteration Act, we find the specific gravity, fat and total solids, and our work is done. But the profession as well as the public may like to know the quantities of the other nutrients in the milk. Milk proteins are of as much importance from the biological point of view as the milk fat; if the latter contains the vitamins, the former contains the amino-acids which are essential for growth. The Kjeldahl process, the usual method for estimating the proteins, is not very suitable for routine work; they can be estimated fairly easily from the aldehyde figures by formol-titration methods, such as those of Steinegger or of Richmond and Miller. But the method which is the subject of

this paper is similar to the one for estimating albumen in the urine by precipitating it with a reagent, it is exceedingly easy, and can be done by any medical man.

We have many precipitants for proteins, and just as in the case of urine we get a fairly workable idea of the amount of albumen from the depth of the precipitate, so in the case of milk there is no reason why a method on the same lines should not be equally useful. In phosphotungstic acid we have a suitable precipitant for milk, especially in the form of Bogg's reagent as given by Kolmer and Boerner (1925), viz,

- | | |
|------------------------------------|--------------|
| (1) Phosphotungstic acid | .. 25 gm. |
| Distilled water | .. 125 c.cm. |
| (2) Concentrated hydrochloric acid | .. 25 c.cm. |
| Distilled water | .. 100 c.cm. |

After the phosphotungstic acid is completely dissolved, the two solutions are mixed and kept in a dark glass bottle. The process of analysis consists of—

- (1) Diluting the milk 1:20 with distilled water.
- (2) Filling an Eshach tube to mark U.
- (3) Adding Bogg's reagent to mark R and inverting several times.
- (4) Setting aside for 24 hours.
- (5) Reading off directly on the scale and multiplying by 2.

I have tried this method on samples of cow and buffalo milk, 10 of each, analysing them also by the Kjeldahl process. The result is given on the next page.

The differences between corresponding figures of the two columns are not significant.

Madras has standardised milk protein as one of the constants under the Madras Food Adulteration Act, 1918 (by Notification II, Order No. 1329-P.H., dated the 4th August, 1926), fixing it at not less than 0.5 per cent. of nitrogen for cow milk and 0.53 per cent. for buffalo milk which are 3.19 and 3.38 per cent. respectively as milk proteins. Stewart and Chatterjee (1931) found that this standard agreed with the result they obtained on 15 samples of milk, fresh and after souring. We have analysed up to date 46 samples of genuine cow's milk and 25 of buffalo milk, each drawn from a separate animal, using the Kjeldahl process for proteins, and multiplying the figures for nitrogen into 6.38; 9 out of our 46 samples of the cow milk and 6 out of the 25 samples of buffalo milk gave figures which are below the Madras standards, but the departures are no greater than those of milk fat in the genuine samples from its legal standards; so the protein may very well be utilised as a supplementary constant; if so, the simple method described above,

(Continued at foot of next page)

COMPARATIVE NOTES ON THE
CRYOSCOPY OF MILK

By EDWIN H. BUNCE, F.I.C., F.C.S.

*Public Analyst to the Government of Burma, Harcourt
Butler Institute of Public Health, Rangoon*

It is well known that osmosis is of fundamental importance in the general metabolism of animal life. The direct measurement of osmotic pressure, however, is a matter of considerable difficulty, and it is more convenient to measure other properties of solutions of known relationship to the osmotic pressure. The depression of freezing point or cryoscopic determination is the most accurate and commonly employed method.

In a case of mammals, milk is the natural fluid for rearing the young, and a study of its cryoscopy is not without interest. Now the osmotic pressure of a given sample of milk is mainly due to the soluble salts and lactose or milk-sugar which it contains. The influence of the fat (the most variable constituent) and the proteins is practically negligible. A certain constancy of the freezing point may therefore be anticipated. Although a number of papers already published on cow's milk substantiate the truth of this statement, references to other mammals of importance are inadequate, and an attempt has been made to supply some necessary data in this investigation.

Only authentic samples from individuals of four different mammals were studied, each accounting for a series of 30 examinations. In

the case of human milk it is important to note that the specimens were drawn 5 to 10 days after parturition, and that both mother and infant were progressing satisfactorily.

A cryoscope of the Beckmann type was employed, the accessories being readily available. Application of correction factors was avoided by a carefully standardised procedure, and no samples showed an abnormal acidity, so that errors were obviated in this respect.

In carrying out the test, the apparatus was filled with a mixture of crushed ice and salt to serve as a freezing medium. A sufficient quantity of the sample (previously cooled) to completely immerse the thermometer bulb was introduced into the freezing tube. The thermometer and stirrer were then inserted. Stirring was maintained uniformly at a rate of about once per second, and the temperature of the cooling bath adjusted, so that a supercooling of the sample between 1.0° and 1.5°C. was readily obtained. The mercury rose rapidly to its highest point when the reading was taken after tapping the upper end of the thermometer two or three times.

The zero point of the thermometer was ascertained by observing the freezing point of recently boiled and cooled distilled water under similar conditions. This point was periodically checked for each new set of determinations.

Tables I, II, III, and IV, give the results and descriptive details, together with the analytical figures relating to the chemical composition of the samples.

* Number of c.cm. of N/10 sodium hydroxide solution per 10 c.cm. of milk.

TABLE V

				FAT, PER CENT.		SOLIDS-NOT-FAT, PER CENT.		* DEPRESSION OF FREEZING POINT, °C.	
				Min.	Max.	Min.	Max.	Min.	Max.
Buffalo	5.02	10.00	9.11	10.72	0.560	0.590
Cow	3.05	6.50	8.70	9.80	0.550	0.580
Goat	1.70	6.75	8.83	10.69	0.550	0.590
Woman	3.10	6.70	8.07	9.90	0.550	0.590

*The 'depression of freezing point' is given in preference to the 'freezing point' in order to eliminate the minus sign.

The figures for solids-not-fat varied considerably in each series, and the fat results showed enormous variation, particularly in the case of goat's milk, where the maximum was four times the minimum. Only the freezing-point figures approached constancy. These facts are brought out clearly in table V.

The results not only demonstrate the constancy of the freezing point within each series, but an extraordinary similarity between one series and another is shown. Human milk is worthy of special notice as it contains a relatively higher percentage of milk-sugar than that of the other mammals under consideration. The quantity of soluble salts present, however, is considerably lower. It would appear, therefore, that the sum effect of these two factors is similar in all four cases, and that the freezing point exhibits a comparatively small range of values.

Dried milk and infant foods

One sample of dried milk (powdered whole milk), and three samples of infant food derived from dried milk were recently received in the laboratory. The former was prepared for use according to the instructions provided (*i.e.*, to regenerate the original milk), and the latter were prepared for feeding as directed for the first week. The usual analysis was extended so as to include the cryoscopic determination as a matter of interest.

The approximate composition of the resulting preparations and the values obtained by the

eryoscopic test are indicated in table VI below :—

TABLE VI

	100.0	100.0	100.0	100.0
Depression of freezing point, °C.	0.580	0.575	0.515	0.195

The extraordinary degree of dilution recommended for 'No. 3' accounts for its relative deficiency in almost all of the constituents and the low depression of freezing point.

[*Note.*—The attention of readers is drawn to a paper published in the *Indian Journ. Med. Res.*, Vol. XVIII, p. 57, on 'The Cryoscopy of Calcutta Milk' by Lieut.-Col. A. D. Stewart and Mr. N. L. Banerjea, of the Calcutta School of Tropical Medicine and Hygiene, who carried out a similar series of cryoscopic estimations. —EDITOR, *I. M. G.*]

A Mirror of Hospital Practice

CYANOSIS AFTER PLASMOCHIN

By R. N. CHOPRA, M.A., M.D. (Cantab.)
LIEUTENANT-COLONEL, I.M.S.

and

B. SEN, B.Sc., M.B. (Cal.)

School of Tropical Medicine and Hygiene, Calcutta

MR. T. E. M., aged 28, European male, was admitted into the Carmichael Hospital for Tropical Diseases on 12th September, 1932, with the following complaints :—

- (1) Cyanosis all over the body.
- (2) Pain in the epigastric region and in the neck.

History.—During the past six weeks the patient had several attacks of malaria. Although no microscopical examination of the blood for malarial parasites was made at that time, the clinical symptoms of rigor and sweating, together with the improvement following the administration of quinine, pointed to a plasmodium infection. The last attack was from 26th August to 2nd September. The fever used to come every alternate day; it was attended with rigors, and subsided with sweating. Treatment outside the hospital was started by his doctor on 30th August; he was given, in all, 53 grains of quinine by the mouth as well as two injections of quinine bihydrochloride, ten grains each, on 30th August and 1st September. The temperature came down to normal on 3rd September and he was ordered to take two tablets of plasmochin (0.01 gramme

each) thrice daily for five consecutive days. He took four tablets on 4th September, six tablets on each of the next four days, and two tablets on 9th September, thus making up a total of thirty tablets or 0.3 gramme of plasmochin.

The patient first noticed he was getting 'blue all over his body' on 6th September, but he thought nothing of it. On 9th September he became very blue, was dyspnoeic, and felt very weak and prostrated. He was getting cold sweats on the forehead, and severe pain in the epigastric region, in the neck and along the back. He had no appetite and was constipated. The drug was discontinued on 9th September, and he felt slightly better, but the cyanosis, although less, persisted and he was admitted to the hospital on 12th September.

Condition on admission.—The patient on admission was markedly cyanosed; the skin and mucous membrane all had a definite bluish tinge. Besides a slight enlargement of the spleen nothing else abnormal was discovered. The heart and lungs were normal. The urine had a specific gravity of 1009 and contained no albumin nor sugar, but gave a strong reaction to indican. Urobilinogen was found in traces, but urobilin could not be detected even on spectroscopic examination.

A fresh blood film showed well-marked crenation of the red blood corpuscles, their colour being dichroic (yellow and green). No parasites could be found in the blood. On spectroscopic examination of the blood, bands of hæmoglobin could be seen, but neither methæmoglobin nor urobilin could be detected. The fragility of the blood was tested, with the following results:—

Initial hæmolysis .. 0.38 per cent. NaCl solution
Complete .. 0.28

This shows that the resistance of the red blood cells was slightly higher than normal.

The patient was put to bed, and given alkalies and mild purgatives daily.

Remarks.—The interesting points about this case are:—(1) The persistence of cyanosis which lasted for over nine days. Usually it disappears 24 hours after the drug is stopped, and very rarely lasts 7 days. (2) Although the blood was spectroscopically examined when the patient was distinctly blue, methæmoglobin, to the presence of which the cyanosis is attributed, could not be detected. (3) The resistance of red blood cells to hæmolytic agents was increased and not decreased, while the patient had plasmochin cyanosis.

TWO CASES OF PITYRIASIS RUBRA PILARIS

By M. N. PAI

CAPTAIN, I.M.S. (T.C.)

Indian Military Hospital, Poona

This disease is comparatively rare in India and the occurrence of two cases simultaneously is of more than passing interest.

Case I.—Sepoy, Umrao Sing, aged 20 years, was admitted into the Indian Military Hospital, Poona, on 22nd December, 1931, for a papular eruption on the body.

Previous history.—Nothing important and no members of his family have ever suffered from it. He used to perspire a good deal after exercise, but on 20th December, 1931, while in camp he caught a chill and next day noticed a papular eruption on the thighs and legs, which rapidly spread to the sides of his chest and abdomen, and the extensor surfaces of the upper extremities.

Condition on admission.—The patient is a well-built young man but with a general dryness of the skin of the body. The affected areas have a well-marked goose-flesh appearance and consist of follicular papules each about the size of a pinhead with a central horny plug surrounding a hair. These papules are well seen over the scapular regions, the extensor surfaces of the arms and forearms, the sides of the chest and over both the lower extremities. A few are also seen on the nape of the neck, but the scalp, face, front of the chest, fingers and the genitalia are completely free, and the palms and the soles do not show any hyperkeratosis. There is no itching or enlargement of glands and the Wassermann reaction is negative.

Microscopically each hair root was found surrounded by a horny plug of desiccated sebum.

Note the distribution of the papules.

Case II.—On 23rd December, 1931, Sepoy Gopal Singh noticed dryness of his thighs followed by the appearance of dry scaly horny papules. These extended gradually over both legs. Five days later he noticed follicular papules on the sides of the chest and abdomen, the extensor surfaces of both arms and forearms as well as over the shoulder blades. As in the previous case the scalp, face, front of chest, fingers, palms and soles are free. There is no itching and the Wassermann reaction is negative.

Differential diagnosis from:—

1. **Lichen Planus.**—This is preceded by itching, affects anterior aspect of trunk, forearms, wrists and genital organs. Papules are hard, shiny, yellowish-red in colour, flattened and depressed in the centre.

2. **Psoriasis.**—The scales are silvery and over-lapping.

3. **Dysidrosis.**—Occurs chiefly on hands and feet, sometimes on face and neck, but the typical aspect is seen on the fingers and itching is well marked.

Treatment.—Thyroid extract and arsenic internally, and alkaline baths externally have been tried with very little success.

Points of interest in these two cases are:—

1. The alleged sudden onset in both cases apparently due to exposure to cold while in camp.

17th July—Temperature—100°F. in the morning fell to normal by the evening. The jaundice became deeper, and he had bilious vomiting. Stools—brownish. Urine—8 ounces in 24 hours, hæmoglobin-coloured and highly acid, a trace of albumen.

Treatment.—Caffeine-soda-benzoas injection, hot water bag over loins, plasmoquine simplex—twice a day, alkaline mixture, etc.

18th July—Morning temperature—97.4°F. Pulse—96. Urine—1 ounce in 24 hours; last urine— $\frac{1}{2}$ ounce at 11 p.m. on the 17th. He had one liquid, bilious motion.

Rectal saline not retained. Pituitrin was injected.

9-30 A.M.—Catheter was passed after giving urotropin, grains 10. Not a drop of urine came out.

10 A.M.—A pint of intravenous alkaline saline was given by the direct method. The reaction was mild and lasted an hour. Adrenaline—minims 10, was given under tongue.

A liquid stool followed but no urine was passed.

11-30 A.M.—Temperature 97°F.

12 A.M.—He took a little milk and pine-apple.

During the temporary absence of the doctor who was watching the case, the patient walked out to the factory, a distance of about 500 yards. He was brought back to his house, where he swooned soon after and died at 1 p.m. from heart failure.

Case 2.—N. Ch. D., Hindu male, aged 20, garden assistant, Gopalpur Tea Estate, fell ill on 26th July, 1932.

Present history.—On 24th evening he went to a neighbouring garden and returned late at night. The next morning he had meat diet. At night he had a heavy meal and retired at 11 p.m. At about 2 A.M. he felt chilly and vomited undigested food. After a while he again got up from his bed and lay on the floor where he passed a stool. The doctor was called at 4 A.M. and he found the boy in a semi-conscious state.

Previous history.—He had been serving at Gopalpur for a year and a half. He had a few attacks of malaria, the last attack was in June 1932. He refused to take quinine regularly under the belief that quinine would produce blackwater fever.

26th July, 1932.—Morning temperature—101°F. Pulse—108. He was slightly jaundiced. Spleen—2 inches. Liver—not palpable. Tympanitis present. Patient drowsy. At 9 A.M. he passed about 4 ounces of hæmoglobin-coloured urine.

The treatment given was much the same as in the previous case. Only about 2 more ounces of urine were passed.

27th and 28th July.—Vigorous treatment was continued on the above lines but only $1\frac{1}{2}$ ounces of urine was withdrawn from the bladder by means of a catheter the first day and less than this on the second. The jaundice increased.

29th July.—The patient was intensely jaundiced—he passed no urine and only $2\frac{1}{2}$ drachms could be withdrawn by the catheter. He was fully conscious in the morning but despite every effort he died that evening at 8-37 p.m. His temperature chart is shown.

Case 3.—M. S., Hindu male, aged 28 years, garden assistant, Gopalpur Tea Estate.

Past history.—He was a malarial subject and had been serving in the Dooars for about 12 years.

Present illness.—He had been suffering from malaria for a fortnight. Since 23rd April, he had low fever in the evening and was taking alkali and quinine mixtures.

On 29th April, the temperature rose to 102.4°F. in the afternoon and in the evening came down to 99°F.

During the small hours of the morning of 30th April, 1930, the temperature rose to 103.6°F. and he passed hæmoglobin-coloured urine.

Spleen—up to umbilicus. Liver three fingers breadth below costal margin. Constipated. Slight jaundice present. Nausea and bilious vomiting.

He was treated on the same lines as the above cases. Intravenous saline produced a violent reaction but in an hour's time 10 ounces of clear alkaline urine was

passed. His temperature rose to 104.8°F. at 6 p.m. when 12 ounces of clear urine was again passed.

1st May, 1930.—Patient passed a restless night. Pulse was irregular. Morning temperature—97°F. Nausea—present. Two ounces of dark-coloured urine was passed at 3-20 A.M.; total in 24 hours had been 4 pints $5\frac{1}{2}$ ounces. After this he passed no urine. His temperature fell below 96°F. at 11-30 A.M. and he became unconscious and died at 12 noon.

A CASE OF ELEPHANTOID PENIS*

By M. G. RAMACHANDRA RAO, M.B. & C.M.

Chief Medical and Sanitary Officer, Maharaja's Hospital, Pudukotah (Trichy.)

THE patient, a student, aged 22 years, complained of thickening of the skin of the penis and scrotum, and enlargement of both.

Previous history.—Four years ago he used to get fever every month, his temperature shooting up to 103° or 104°F., and lasting about 12 hours. The fever started with a rigor, and pain all over the body. He had a burning sensation in his scrotum and penis. He had a course of sodium cacodylate injections and was relieved of the attacks for one year.

History of present illness.—The present condition started two years ago as a lymphangitis of the scrotum and penis, temperature running up to 104°F. and lasting

I. Before operation.

for about eight hours. Such attacks came on every month. At every attack he had swelling and tenderness in the scrotum and penis; the swelling increasing with each attack. He had an attack in October, but was free for six months from January to June 1931. He had a course of fibrolysin injections.

Condition on admission.—There is elephantoid thickening of the scrotum and penis. The skin is $\frac{1}{2}$ to $\frac{3}{4}$ inch in thickness; the skin of the penis is involved up to its root, and cannot be retracted. The meatus is not seen. The penis is shaped like a ram's horn, and the distal third is curved with the concavity of the curve pointing upwards, as seen in the illustration.

The length of the penis is about 8 inches from the tip to the root. The ram-horn curving of the penis has only occurred during the last year, and was not present from the start. The glans penis can be felt in the distal third of the elephantoid penis. When he passes urine

* Rearranged by the Editor.

2. Absence of tuberculous diathesis.
3. Absence of the characteristic papules on the scalp, face and front of chest.
4. Absence of hyperkeratosis of the palms and soles.
5. Absence of changes in the nails.

My grateful thanks are due to Col. E. C. Hodgson, D.S.O., K.H.P., I.M.S., Officer Commanding the Indian Military Hospital, Poona, not only for his kind advice but also for permission to publish the notes on these two cases.

THREE FATAL CASES OF BLACKWATER FEVER*

By C. C. DAS GUPTA, M.B.

Chief Medical Officer, Gopalpur Group of Tea Estates
Gopalbagan, Jalpaiguri

DURING the last ten years in the Dooars, I have treated a number of cases of blackwater fever, but the cases I am reporting here are in

to be blocked so completely that after saline not a drop of urine is secreted.

Case 1.—Boka, Chinaman, male, aged 50, carpenter, Gopalpur Tea Estate, got blackwater fever on 16th July, 1932.

Present illness.—At 11 A.M. he passed three ounces of hæmoglobin-coloured urine. His temperature was 105°F., pulse 116, and respiration 36. He had intense jaundice. His bowels were constipated, and tongue coated. The liver and spleen were not enlarged.

Past history.—He had lived in the Dooars for 18 years and had had 8 attacks of blackwater fever, the last attack was on 3rd October, 1931. He was a malarial subject and did not take quinine as a prophylactic.

On 7th July, 1932, he had an attack of malaria and was put on saline purge, alkali and quinine. He got well in a few days and resumed his duties.

16th July, 1932—Treatment—(1) An initial purgative containing calomel—grs. 2 and sodium bicarbonate—grs. 10, followed by magnesium sulphate at bed time, was given.

(2) An alkaline mixture—a combination of sodium bicarbonate, potassium citrate, liquor hydrargyri perchloridi and extractum punarnavæ liquidum—every 2 hours.

Name... N.C. Das. Age... 20. Disease... Blackwater Fever.

a class by themselves and in spite of every possible treatment ended fatally.

This season cases are occurring which start with anuria and die of uræmia, in spite of intravenous alkaline saline. The kidneys appear

(3) Rectal saline—sodium chloride—90 grains and sodium bicarbonate—160 grains to the ounce of water—6 ounces every 2 hours.

(4) Calcium chloride—grs. 4 in 10 cubic centimetres glucose solution was given intravenously.

(5) Plasmoquine simplex—1/6th grain—one dose.
Diet—green-cocoanut water, soda water, glucose and sodium bicarbonate drink.

JANUARY

RECENT RESEARCHES ON BLACKWATER FEVER

A VERY important memoir which has recently appeared on the subject of blackwater fever is that by G. R. Ross (1932), Rhodesian Research Fellow of the London School of Hygiene and Tropical Medicine, entitled 'Researches on Blackwater Fever in Southern Rhodesia'. This memoir is very comprehensive, both in its survey of the previous literature and in its account of the investigations in Rhodesia carried out by the author and his collaborators. It constitutes an extension of the now classical memoir by Thomson in 1924.

The white occupation of Southern Rhodesia dates from 1890 and the successful development of the country has been dependent on the two primary producing industries of mining and agriculture. The white population numbers 44,950, of which some 8 per cent. are engaged in mining industries, 17 per cent. in agriculture, and 75 per cent. in transport, industrial, commercial and professional duties. This last element is largely concentrated in the four large towns of Salisbury, Bulawayo, Gwelo and Umtali in which approximately 47 per cent. of the white population live. Males largely outnumber females, and owing to the immigration of young adults the percentage of the white population over 15 years of age is greater than it is in the standard British million. The native population numbers 933,899, of which 760,301 live in the native 'reserves' and 173,598 live and work in close proximity to the white population.

As the result of Thomson's work on the subject in Southern Rhodesia in 1922 and 1923 a standard system of notification of blackwater fever cases was introduced (although not made compulsory), and this greatly helped Dr. Ross in collecting data. Between the years 1914 and 1928 inclusive 679 cases of blackwater fever were treated in Southern Rhodesian hospitals with 152 deaths, a case mortality of 22.2 per cent. The average death rate among the European community between 1924 and 1928 was 9.25 per mille, of which blackwater fever, notified as such, accounted for 2.2 per cent. of the total deaths. The disease is nearly four times as common among European males as among European females, but the population of the latter only numbered 17,366 in 1926

which would account for the discrepancy. Essentially, blackwater fever attacks those engaged in the rural areas—the case incidence per mille being 3.01 for those engaged in agriculture, 2.83 for the mining industry, and 2.07 for transport workers; 1.42 for rural areas, 1.32 for rural townships, and 0.28 for urban areas of over 1,000 population.

In summing up the first section of the memoir, on the distribution and incidence of the disease in Southern Rhodesia, Dr. Ross writes as follows:

'The essential fact which has emerged in the study is, probably, the realization of the intimate association of the disease with rural conditions. The higher incidence of the disease in rural inhabitants as compared with urban inhabitants generally, and the high incidence in those engaged in pioneer occupations, both help to establish this fact.

The differential distribution in urban and rural districts deserves to receive emphatic mention, since it is an encouragement to the hope that the disease may yet be more fully controlled. This history of the four big urban centres shows that in the earlier years of the colony, blackwater fever was not always the comparatively rare disease that it is to-day. Perhaps the most illuminating part of the story of their achievement of relative immunity is the realization that this has come about, not because of special control measures against the disease, but as part and parcel of their general economic and municipal development. That this should be so, is surely sufficient encouragement for the belief that as development in the country districts proceeds we may look for a lowered incidence of the disease in the next, if not in the present generation. Further, the application of methods of control, based on conclusions reached by the scientific study of the disease, must assuredly promise a speedier path to the desired consummation.

This definite distinction between urban and rural areas must enter largely into the consideration of several features of the distribution of the disease as revealed in the preceding pages. Thus the fact that the incidence is greater in males than in females may be explained, partially at least, by the fact that men are much more likely to engage in the occupations which bring them into contact with primitive and undeveloped country. Farming, mining, prospecting and transport work which supply so large a percentage of the cases of the disease, are still almost entirely the undisputed territory of man in Southern Rhodesia. At the same time it must be acknowledged that wives and other female relatives do in many instances share the hardships and primitive environment under which these industries are conducted. There is no method of obtaining the relative figures of females so placed or calculating the incidence of the disease in them, but the cases of the disease recorded in females for the period have occurred almost exclusively in this class.

Another factor which may account for the difference in incidence in the two sexes is the fact that men are much more careless in their habits and methods of life than women. The flimsy and primitive housing arrangements, the monotonous and inadequate dietary that consists mainly of tinned products and ignores such essentials as fresh milk or vegetables, and the general disregard of comfort-making amenities, that so often characterize life under masculine management, are not tolerated by women, if anything better is possible, and their influence in raising the general standard of life cannot be minimized. That they generally insist on a high standard may be one reason why the incidence of the disease amongst them is less.

As far as the age-distribution of the disease is concerned, attacks may occur at any age, but the figures for the period have shown the disease to be rare in

* Ross, G. R. (1932). Researches on Blackwater Fever in Southern Rhodesia. No. 6 of the *Memoir Series of the London School of Hygiene and Tropical Medicine*. Price: cloth 10s. 6d.; paper 8s.

those under 5 years of age and to be commonest in the years of adult life, particularly from 15 to 34. The explanation of the low incidence in the years of childhood probably lies in the fact that much greater care and attention are very naturally lavished on children who are thus protected from unhealthy circumstances as far as possible, and that the majority spend a large proportion of their childhood in the schools which are mostly situated in the non-endemic urban areas. The increased incidence in adult years is probably accounted for by the fact that it is during these years that occupations are engaged in which spell risk as far as blackwater fever is concerned.

The incidence of the disease in the Rhodesian-born is illuminating in this connection, for it is seen that the chances of contracting the disease are small until an age is reached when economic circumstances force them to seek employment, and to look after themselves.

The relationship of length of residence to the development of the disease involves considerations which are different from those discussed above, for the establishment of the fact that the disease only occurs after a certain length of residence is bound up with the question of the aetiology of the disease in a more intimate way than the distribution of the disease amongst the various sections of the community. The figures obtainable for the five years have shown that the greatest percentage of first attacks occurs during the first five years of residence, that the disease has been uncommon in those with less than one year's residence. These findings are in agreement with experience elsewhere, but it is hardly possible to discuss any explanation of why this should be so without reference to other considerations which have not yet been discussed.

The author passes next to a consideration of the relationship of blackwater fever to meteorological conditions in Southern Rhodesia. In general, the incidence of the disease reaches its maximum about three months after the period of maximum rainfall (October to March). Correlation with temperature is less marked, though the incidence tends to be highest in those regions with highest temperature. 'Viewing the subject as a whole, the impression that is gained is that the influence that meteorological conditions exert upon the disease is not a direct one, but is dependent upon the activity of some other factor upon which they react'.

Chapter IV of the memoir deals with the relationship of blackwater fever to malaria, and here we reach the crux of the whole question. The accumulated evidence in this chapter is conclusive that blackwater fever is a manifestation of malaria. Deeks and James (1911) in Panama were perhaps the first to stress this point. Schilling (1911) in German East Africa also drew attention to it. In some areas, such as the Punjab and the Philippine Islands, we get intense malaria without blackwater fever, but in the former, malaria is strictly seasonal in its incidence and the population is not exposed to infection throughout the year, whilst in the latter, malaria control and continued treatment are fairly well enforced. In Rhodesia malaria is not a notifiable disease, and very many cases do not come to hospital. On the other hand chart 14 of the memoir shows how extremely close is the correlation between hospital admissions for the years 1924-1928 from malaria and those from blackwater fever,

whereas the curves for admissions for typhoid fever and pneumonia show no such correlationship at all. (This graph confirms and extends an exactly similar set of observations recorded in Thomson's memoir of 1924.) Chart 12 in the memoir shows again an extremely close correlationship between the prevalence of the local anophelines, which reaches its maximum in March, and blackwater fever, which reaches its maximum in April. The malaria of Southern Rhodesia is almost exclusively due to *Plasmodium falciparum*, whilst of the 14 species of Anopheles present, the two really important ones are *A. funestus* and *A. gambiae*, whose prevalence again shows a very close relationship to that of blackwater fever, and which alone on mosquito dissections proved to be malaria-infected. The work of Napier and Campbell (1932) and of Knowles and Das Gupta (1932) shows that hæmoglobinuric fever may occur as a terminal event in monkeys of species *Macaca mulatta* dying from monkey-malaria, and again emphasises the close relationship between plasmodium infections and blackwater fever.

It must be admitted on the whole that the 'malaria hypothesis' with regard to the etiology of blackwater fever now holds the field to the exclusion of any other. (The reviewer has tried to hold an open mind on this subject for years, but is now forced to the conclusion that this hypothesis is the correct one.) The association is usually with *P. falciparum* infections, and that in an endemic or hyperendemic area, but sometimes the other species are concerned. Thus, Giglioli (1930) stresses its connection in British Guiana with *P. vivax* infections, whilst workers in the Dutch East Indies have found it associated with *P. malariae* infections.

If blackwater fever is a manifestation of malaria, it is due however to malaria plus some other factor or factors. What this factor or these factors are at present we do not know. There may be exaltation of the virus by constant passage through aboriginal tribes in the locality who have become habituated to it; it may be associated with certain groups of transmitting anophelines; it may be precipitated by quinine (but not necessarily so in all cases); it may be due to biological or biochemical causes in the individuals concerned. The future study of the disease in experimental monkeys may help us in investigating these factors.

With regard to the association of blackwater fever in Southern Rhodesia with malaria, Dr. Ross writes as follows:—

'As far as Southern Rhodesia is concerned the relationship existing between malaria and blackwater fever in that territory must be regarded as adding considerable weight to the argument that the latter disease is a manifestation of infection with malignant tertian malaria. It has been seen that the greatest incidence of blackwater fever occurs in those classes of the population and in those areas in which the incidence of malaria is greatest, that freedom from malaria and blackwater fever go hand-in-hand, that the seasonal

incidence of the two diseases is similar, that evidence of previous malarial infection exists in practically every case of blackwater fever, and that there is an intimate association between an attack of acute malaria and an attack of hæmoglobinuria. The collective weight of these facts must surely emphasize the importance of malaria in the genesis of the disease. How far infection with other varieties of the malarial parasite can predispose to the development of blackwater fever cannot be determined from the information obtainable from Rhodesia, where malignant tertian malaria alone accounts for practically all cases of malaria seen.

If one takes certain features of the epidemiology of the two diseases, particularly the distribution in the population and the seasonal incidence, the similarity which has been demonstrated might be explained by a common vector. Thus the transmission by *Anopheles gambiae* or *Anopheles funestus* of a hypothetical blackwater-fever virus, in addition to the malarial parasite, would explain the absence of both diseases from districts in which these mosquitoes were absent and the occurrence of the epidemic phases of both diseases at the same time of year. Such an assumption, however, cannot explain the infrequency of blackwater fever in the first year of residence or its development at considerable intervals after removal from an endemic region unless one postulates qualities in the virus or agent of a most unique nature. Nor can it explain the immunity of the native inhabitant or the frequency with which an attack of malaria precedes the attack of blackwater fever.

The conclusion reached by Leishman (1912), Deeks and James (1911), Stephens (1915), Thomson (1924), and many other observers that blackwater fever is a manifestation of malarial toxicity is one which the results of the present investigation substantiate.

With regard to the rôle of quinine, Dr. Ross reports in all on 162 cases, which gave the following history:

No quinine taken for at least one week prior to the onset of blackwater	11 cases.
Patients regularly taking prophylactic quinine	20 "
One dose only of quinine taken prior to the onset of blackwater	31 "
Hæmoglobinuria developed after several doses of quinine had been taken	100 "

'The obvious irregularity in the relationship of quinine to the attack', he writes, 'in so great a number of cases presents a perplexing problem if we are to regard quinine as an important factor in the actual genesis of blackwater fever and suggests that the mechanism whereby the effect is produced is of a complex nature'.

The author deals next with other subsidiary factors. The Rhodesian cases do not bring out exposure to cold or fatigue as exciting causes. In some instances a well-marked familial history was obtained (but this may be due to members of the same family residing in the same house). A history of previous attacks is common—73 out of 192 cases reported, or 38 per cent. It is well known that blackwater fever is frequently a household or site infection, the type of house concerned being usually one that affords ideal facilities for resting mosquitoes.

Part II of the report deals with the biochemistry of the blood and urine in blackwater fever. Here, again, there is an admirable summary of all previous work and views, and a large volume of original work reported on. It is impossible to summarise this section of the report, since it is itself of the nature of a review, and should be read in the original by all workers interested in the disease. Part III of the memoir is concerned with clinical types of the disease, its prophylaxis and treatment. Such types are exemplified as mild to moderate and uncomplicated, fulminant and toxic types, the anuric type, the continued and intermittent type. Of 118 cases the duration of the hæmoglobinuria was as follows:

Up to 24 hours	29
1—2 days	28
2—3 days	27
3—4 days	16
4 days or longer	18

Relapses were not infrequent—10 per cent., as compared with a figure of 13 per cent. for a series of cases in Uganda. The opinion is often expressed that blackwater fever patients should not be moved to hospital as this increases the risk run. Dr. Ross finds that the reverse is the case; the case mortality among those moved to hospital was 27 per cent. as against 32 per cent. for those not moved; the greater nursing facilities in a good hospital more than compensate for the risk incurred in moving the patient.

With regard to symptoms, rigor may be absent—48 cases, may precede the hæmoglobinuria—104 cases, or follow it—10 cases. The administration of quinine has no effect on the pyrexia accompanying the hæmoglobinuria or upon 'post-hæmoglobinuric pyrexia'—the pyrexia itself being apparently a manifestation of the hæmolytic process. Hiccough is common in the anuric and toxic cases and is a very grave symptom. Lumbar pain is very frequent and would seem to be definitely of renal origin. Pain over the hepatic area and spleen may also be complained of. Splenic enlargement is usual but not invariable in the disease.

With regard to treatment, there are so many 'treatments' in vogue that it may be said at once that none of them has any special merit. The mortality in the disease remains at a figure of about 25 per cent., no matter what treatment is adopted. Injections of hæmostatic sera, of horse serum, of antivenene, and blood transfusion have all been advocated, but the benefit of all seems doubtful. Calcium chloride may be anti-hæmolytic in the test tube, but it is more than doubtful whether the amount injected could achieve the same effect in the human body. Intramuscular injections of caffeine sodium benzoate were tried out in a series of the Rhodesian cases, but of 20 cases so treated 8 died. 'The conclusion reached by most

observers who have had to undertake the treatment of blackwater fever is, undoubtedly, that we possess no remedy which can be accepted as having demonstrable influence on hæmolysis, and this conclusion is reflected in the fact that the treatment most generally employed in the disease is purely symptomatic'.

'To endeavour to produce diuresis is undoubtedly physiologically sound', writes the author. Sodium bicarbonate has been used extensively in the treatment of the disease for a variety of reasons. 'The alkaline treatment of blackwater fever has received most extensive publicity and there is some danger of its being regarded as a panacea. One fact, however, deserves emphasis. Despite the number of authors who have published their findings the total number of cases covered by their reports is small..... There is thus ample justification for the critical to wonder whether the ordinary probability of recovery is sufficiently allowed for..... If alkaline therapy is used, the oral or rectal route is to be preferred to the intravenous. Intravenous injections of large quantities of sodium bicarbonate are undoubtedly dangerous and may cause tetany and even death..... In Southern Rhodesia the intravenous injection of bicarbonate in cases in which symptoms of suppression were present was attended by disappointing results. Used in the strength of 150 grains to the pint, the injection of 1 and 2 pint amounts was ineffectual in preventing the development of suppression in three cases of the anuric type'. Further, in blackwater fever, although there has been a loss in the corpuscular volume of the blood there has been no corresponding loss in the plasma, and there do not appear to be special indications for intravenous saline injections. Blood transfusion would appear to be much better. Treatment after the cessation of hæmoglobinuria resolves itself into treatment of the anæmia and of the resulting debility. Iron and arsenic are universally employed in this condition, whilst treatment of the anæmia with liver extract is also worthy of trial.

With regard to the very vexed question of whether the administration of quinine is advisable or justifiable during blackwater fever or not, it seems impossible to give a definite opinion. The largest collection of figures on this point is that given by Thomson (1924) compiled from the statistics of Deaderick and Cardamatis: in 1,931 cases treated with quinine the mortality was 25 per cent., whereas in 898 cases treated without quinine the mortality was 10.3 per cent. (It seems possible that in atabrin we may now possess a drug which will clear up the malaria infection underlying the blackwater fever without any danger of increasing the hæmolysis.) After recovery from the attack of blackwater fever, anti-malaria treatment must be given, or the patient will get a relapse—either of malaria or of blackwater fever,

With regard to prophylaxis, the position is the same as that with regard to malaria. In the tremendously widely scattered rural areas of Southern Rhodesia larval species control is an immensely difficult problem; and individual prophylactic measures (amongst which the administration of plasmoquine for its 'crescenticidal' effect will certainly take its place) seem to be more feasible. The screening of houses is not merely advisable, but is a necessity. In this connection Dr. Ross writes as follows:

'It is obvious that no campaign against malaria can be planned without knowledge of topographical circumstances, of the distribution and nature of the exposed population, the habits of the carrier mosquitoes, and the economic problems involved. In Southern Rhodesia we have to deal with an extensive territory in which the exposed population is small, widely scattered, and consists mainly of two races differing greatly in their habits and circumstances. Moreover, it has been shown that the disease is essentially rural in its distribution and that it exhibits a seasonal periodicity which is closely related to the prevalence of *Anopheles gambiae* and *Anopheles funestus*. It has further to be remembered that the country is still in the initial stages of its growth and development, and that, however great the desire to be rid of malaria, there is a limit to the expenditure which can be devoted to the object. Taking these facts into consideration, it does not seem probable that extensive anti-larval measures will be instituted in the near future. If the problem were the elimination of malaria from such towns as Salisbury and Bulawayo one would not hesitate to recommend such schemes for favourable consideration, but when the main endeavour must be to protect the scattered rural population economic problems are likely to cause the postponement of a national effort to a more prosperous time. This applies most particularly to drainage schemes, the value of which is not challenged, and where individuals or companies are in a position to embark on such schemes the expenditure would undoubtedly be justified.

Alternative methods of larval control involving the employment of such larvicides as oil or Paris green seem more suitable to the requirements of the country. The investigations on mosquito prevalence in Rhodesia suggest that such measures are only essential during the rainy season and for a short period at the commencement of the dry season, and they may be recommended as more likely to achieve a quicker and more extensive result under present conditions than any other anti-larval measure.

While the merit of anti-larval measures remains unquestioned, it would appear that considerable time must elapse before such measures will effect any considerable reduction in the mosquito population of the colony, and that, meantime, the inhabitants in rural districts must depend upon more personal methods of prophylaxis.

While on the whole, the standard of education in the colony is such that the elementary facts of the mosquito-malaria doctrine do not require stressing, there is urgent need for the instillation of a more wholesome respect for the consequence of malarial infection. The general attitude towards the disease is much too complacent. It is regarded as a demon not half so black as terroristic medical men would paint it, and its exorcism by an occasional dose of quinine as a matter of simple household therapeutics. Until such time as the individual is brought to realize that malaria is an insidious, treacherous and death-dealing disease, only a half-hearted response may be expected from those whose co-operation is an essential in any campaign against it,

Much greater attention should be given to the choice of building sites and the construction of mosquito-proof houses. The choice of sites situated as far as possible from possible anopheles breeding grounds, the clearing of scrub vegetation, and the removal of native compounds to a distance of at least 400 yards on the leeward side are elementary precautions which all should observe. As far as actual construction is concerned, the necessity of screening part of the house at least should be recognized, while mosquito-nets should be regarded as an essential furnishing.

The London School of Hygiene and Tropical Medicine is to be congratulated on the publication of this admirable report. Within its 262 pages it summarises our present-day knowledge of blackwater fever, with special reference to rural areas, and emphasises the lacunæ in that knowledge. It should serve as a starting point from which further investigation will commence.

SPLENECTOMY. INDICATIONS AND RESULTS, WITH SPECIAL REFERENCE TO CONDITIONS OBTAINING IN THE TROPICS*

By SM FRANK CONNOR, D.S.O., V.H.S.
F.R.C.S., D.T.M. & H.
COLONEL, I.M.S.

A. D. M. S., Bombay District; late Professor of Surgery, Calcutta Medical College

It is proposed to bring before you, very briefly, some facts with regard to the subject of splenectomy, with special reference to tropical countries. This must include some account of the enormous and complicated subject of splenomegaly. The short notice I have received to join in this discussion is quite inadequate for a full account of this subject.

In order to interpret correctly the indications for splenectomy, we must have sufficient knowledge to unravel the clinical and pathological evidence which comes before us. This knowledge is to a great extent in the making, more especially in the tropics. Taking India as an example of the tropical and sub-tropical world, we find an enormous amount of material for investigation. What is wanting, however, is the necessary co-operation between the physician, surgeon, and pathologist. My own small efforts to elucidate the subject from a surgical point of view and my long connection with medical colleges in India have shown me that India is very backward in this respect. Most valuable clinical and research work has been done, but with little effort towards collaboration.

In Egypt surgeons number their splenectomies by the hundred, but they have the advantage

of dealing with a definite clinical entity, Egyptian splenomegaly. But even in this disease the pathology has not been accurately worked out, although its association with *Bilharzia mansoni* seems to be established. The splenomegaly of chronic malaria and kala-azar, when it approaches the so-called splenic anæmia stage, would appear to be of a closely allied type.

From the point of view of the patient we can unhesitatingly state that he is entitled to surgical treatment for splenomegaly as soon as it is apparent that therapeutic measures are of no avail, provided that the surgeon after weighing the indications for operative treatment can offer him a reasonable chance of improvement or cure. Although our knowledge is making rapid strides, it is true to-day that the surgeon is not in a position to be able to say in every case whether splenectomy offers the patient the best hopes of recovery. Two essential factors have still to be worked out, namely, earlier and more accurate diagnosis and a more successful procedure for dealing with fibrosed spleens with extensive adhesions.

It is not intended to deal at any length with the indications and results of splenectomy for such conditions as injuries, displacements, abscesses, tumours and cysts. These present few features of peculiar interest in tropical countries. India is the land of *ruptured spleens*, because of the enormous incidence of malarial enlargement. Chevers (1870) noted as far back as 1866 that among 33 police autopsies in that year in one small district (Jessore), six were cases of ruptured spleens. The accident is more common during the months of highest malarial incidence, August to November. It is well known that malarial and kala-azar spleens may be ruptured by comparatively trivial

* Read in the Section of Surgery at the Centenary Meeting of the British Medical Association, London, 1932.

violence, and that so-called spontaneous rupture may be caused by such slight muscular effort as turning over in bed.

In a series of 45 consecutive cases of ruptured spleens treated by splenectomy collected from the records of three hospitals in India and Burma the difficulties of exact diagnosis are evident. Pain, tenderness, and localized dullness in the left flank are the most reliable signs. The character of the pulse and the presence or absence of rigidity or distension are not of great diagnostic value. It is obvious that the symptoms and signs in each case will depend much upon the size and consistency of the spleen, its degree of fixity, and the nature of the violence. In 22 cases of this series in which the nature of the violence is recorded, the rupture was due to crushing in 7, falls in 6, blows in 7, stabs in 2, and in one case of sarcoma the rupture was said to be 'spontaneous'. It must be borne in mind that in the tropics a large proportion of ruptures occur in spleens already enlarged by disease. The results of splenectomy in these 45 cases was: recovered 26, died 19. The best results were obtained among those operated on promptly, that is to say as soon as the effects of the primary shock had abated. Transfusion would undoubtedly have saved some lives, but this procedure is not always possible in India. Several cases in

was much elongated and twisted two and a half times, so that the notched border lay posteriorly beyond the reach of palpation. The viscus was greatly distended with blood and the splenic vessels were very large; in one case strangulation had threatened on two occasions.

Abscesses, cysts, and new growths of the spleens are all rare conditions. The pus in abscesses is usually grumous or thick and creamy, and is most often sterile on culture. Hæmorrhagic cysts may result from the breaking down of soft malarial spleens and later on these may degenerate into abscesses. Hydatid cysts are very uncommon as are all varieties of new growth; in one case of sarcoma of the spleen, referred to again below, the organ weighed 15 lbs. 14½ oz., and invaded the ribs and surrounding structures with secondary growths in the kidneys.

Three groups of post-mortem cases will now be discussed with the object of trying to elicit information as to the ætiology of splenomegaly in the East. They comprise over twelve hundred cases of enlargement of the spleen occurring among 3,308 consecutive deaths from all causes. Many cases of splenomegaly in which death occurred from rupture or other causes soon after admission into hospital have escaped notice here, as the necropsy was performed in the police morgue.

TABLE I

	Series A (Bengal) 1920—1929: 977 cases. Minimum wt., 200 gm. Highest wt., 2,700 gm. Spleen enlarged, 54 per cent. Based on ante-mortem diagnosis	Series B (Bombay) 1927—1931: 700 cases. Minimum wt., 150 gm. Highest wt., 2,030 gm. Spleen enlarged, 40 per cent. Based on autopsy findings	Series C (Rangoon) 1927—1931: 1,631 cases. Minimum wt., 200 gm. Highest wt., 8,144 gm. Spleen enlarged, 29 per cent. Based on autopsy findings
Malaria	31	49 (including 7 ruptured)	30
Kala-azar	67	1	1
Portal cirrhosis	19	..	40 (17 with ascites)
Acute infections, etc.	104	42	241
Tuberculosis	88	..	85 (11 involving spleen)
Leukæmia	3	1	1
Hodgkin's disease	1	2	..
Pernicious anæmia	4	..
Heart disease	38	9	31
Splenomegaly of doubtful ætiology	26	2	1
Sarcoma of spleen	2
Miscellaneous	148	170	38
TOTAL ..	525	280	470

which the extravasated blood was re-injected into the patient during the laparotomy appeared to be greatly benefited.

Very movable or wandering spleens are more often met with in tropical than in temperate countries, as would be expected. The difficulties of diagnosis in some instances are considerable. Two very large spleens of this type were operated on by me as undiagnosed tumours and both did well. The pedicle in each case

These three groups of splenomegaly are compared with difficulty, because they are not all classified on the same basis. A brief analysis will however be attempted.

Series 'A' includes 525 cases of enlarged spleen found in 977 autopsies (54 per cent.), taking 200 grammes as the minimum for enlargement, from the Pathological Department, Calcutta Medical College, collected by M. N. De (1932). The classification given above in

table I is based on the ante-mortem diagnosis, but the following is a brief summary of some of the autopsy findings as analysed by De :

(1) There are 54 examples of splenomegaly in the whole series in which the weight of the spleen varies between 600 grm. and 2,700 grm., and in these the post-mortem findings are as follows :—

Kala-azar cirrhosis	14
Splenic anæmia	2
Kala-azar or chronic malaria suspected, but not confirmed	21
No definite diagnosis	17

De states that these 17 cases of unknown ætiology and the 21 diagnosed as malaria or kala-azar without post-mortem confirmation, form a natural group presenting a recognizable clinical history :

‘They are commonest in the western and the lower part of East Bengal and run a chronic course, with gradual enlargement of the spleen and liver accompanied by irregular fever. Ordinary therapeutic measures are of no avail. They develop a secondary anæmia with leucopenia and a reduced polymorph count; fibrosis of the liver develops leading up to ascites. Death supervenes from some inter-current malady, such as pneumonia, colitis, etc.’

The morbid anatomy and histopathology of the same group of cases with very large spleens is described by De as follows :—

‘The spleen is tough on section with prominent trabeculae, and perisplenitis and adhesions are common; the liver is congested, fibrosed, or cirrhotic (lobnailed); red formative marrow is found in the middle third of the femur. Histologically: the spleen pattern is lost and the Malpighian follicles atrophied; the pulp cellular and filled with many large phagocytic cells; red cell phagocytosis may be prominent. The capsule and trabeculae are found thickened with increase of coarse reticular fibres’.

If the existence of this natural group of very large spleens, with characteristics as described by De above, can be confirmed and it can be proved that such cases are recognizable by clinical or other tests, then the possibility for a large field for splenectomy comes into view. What would be the results of surgical interference remains to be seen, but this will probably depend mainly on two factors: the possibility of raising the patient's powers of resistance before operation, and the improvement of the existing technique for dealing with extensive splenic adhesions.

If we proceed to criticize the pathological findings of De in these 54 cases of greatly enlarged spleens, the striking fact is observed that none of them are accepted as cases of chronic malaria. Malaria is known to be common in Bengal and to be associated with considerable splenomegaly, and it seems fair to conclude that a certain number of cases are included in this group of undiagnosed cases.

T. A. Hughes and D. L. Shrivastava (1931) have published a report of 31 cases of anæmia in patients with splenomegaly, which is ascribed to chronic malaria although no signs of active malaria or parasites were present. In the absence of parasites and of active malaria and in some other respects these cases resemble De's group of undiagnosed splenomegalies. Hughes and Shrivastava describe their series of cases further as follows: they were all admitted into hospital with a clinical history of repeated attacks of fever followed by progressive weakness, intensified by the discomfort of carrying very large spleens; in some cases the liver was also enlarged, and in two which reached the post-mortem room the spleens presented the typical appearance of chronic malaria. A detailed report is given of the blood examination of these patients by Hughes and Shrivastava, and it is concluded that in the milder cases the blood condition is due to the destruction of the erythrocytes by the reticulo-endothelial cells of the spleen and possibly of other organs, facilitated in some cases by the abnormal fragility of the corpuscles. In severe cases there is evidence of derangement of the bone marrow. While malaria is given as the primary cause of this type of anæmia associated with splenomegaly, it is suggested that there are also aggravating causes such as dietetic deficiencies, the strain of pregnancy, etc. Of four cases treated with liver and iron improvement took place in three, but in the fourth no improvement occurred in the red cells or hæmoglobin, although there was evidence of bone-marrow activity, suggesting that blood destruction kept pace with blood regeneration. This view was supported by the behaviour of the plasma bilirubin. Splenectomy was not performed for any of this series, but it would certainly appear a reasonable procedure in cases such as these where the spleen is dominating the pathological situation instead of subserving useful functions. A further argument in favour of splenectomy is that it is in accordance with experience that patients of this type improve while under therapeutic treatment, but retrogress as soon as this is discontinued.

The characters of the splenomegaly of kala-azar must also be considered in connection with the ætiology of doubtful cases of splenic enlargement. It is generally stated that in kala-azar the spleen has a thickened capsule and the microscope shows an increase of fibrous tissue, but this is not borne out by critical examination of active cases. In a series of 31 cases of enlarged spleen occurring during a period of nine years, the connective tissue and reticulum of the liver and spleen were carefully studied by Shanks and De (1931). The greatly enlarged spleens were found to be chiefly due to kala-azar, and in 25 the parasite was identified. In 23 of the parasite-positive cases no increase of the fibrous tissue or reticulum was demonstrable, while in 5 parasite-negative cases

there was evidence of fibrosis. In 70 per cent. of the same positive series there was no increase of the fibrous tissue or reticulum of the liver. These soft positive kala-azar spleens are wonderfully responsive to therapeutic measures and the question of splenectomy does not arise, but it is known that in more chronic cases the spleen may become much more fibrous and diminish little in size under treatment (Napier). Christophers refers to patients with very large spleens without parasites, but resembling cases of kala-azar in every other respect; and others without any clinical resemblance to kala-azar, but with a splenomegaly exactly like that of kala-azar.

These post-malarial and post-kala-azar splenomegalies are well worthy of a close study among the group of cases of doubtful aetiology from the point of view of treatment by splenectomy. These are some of the cases which would appear to degenerate into the 'splenic anaemia' stage and become a menace to health.

Before leaving the Bengal group of 525 cases of splenomegaly it is interesting to note that there were 26 cases in which accessory spleens were present; and that in 203 instances fibrosis of the spleen was a prominent feature, with thickened capsule, peri-splenitis, adhesions, thickened trabeculae, dull to dark red colour. There was no evidence of any direct relationship between the degree of enlargement and the amount of fibrosis.

Series 'B' (Bombay) includes 280 cases of splenomegaly in 700 consecutive autopsies (40 per cent.), taking 150 gm. as the minimum weight, collected by P. V. Gharpure at the Pathological Department, Grant Medical College, Bombay. The classification adopted by Gharpure (see table I) is based on the post-mortem findings and is not intended to be a complete analysis of the cases. Its object is to compare and contrast the Bombay group with the Bengal group, especially as regards the incidence of malaria, kala-azar, portal cirrhosis, and splenomegaly of unknown origin.

The series presents some interesting features of its own. There are no cases of kala-azar, and it is known that this disease is absent in the western half of India. Chronic malaria with fibrosis of the spleen is responsible for 45 cases (16 per cent.) of enlargements, and it is stated that peri-splenitis and adhesions are usually present in this disease. Cirrhosis of the liver was not found associated with splenomegaly, and the high incidence of malaria suggests the conclusion that malaria is not a causal factor in the production of cirrhosis of the liver.

Series 'C' (Rangoon) comprises 470 cases of splenomegaly among 1,631 autopsies performed at the Rangoon General Hospital (29 per cent.). A rough classification has been attempted based on the cause of death found at the necropsy. Acute or chronic malaria accounts for 30 cases (6 per cent.), and this

series like the Bengal series shows a high incidence of cirrhosis of the liver with or without ascites, 40 cases (9 per cent.). Tuberculosis, probably in most cases an intercurrent affection, accounts for 85 cases (18 per cent.), and acute affections and miscellaneous conditions together total 59 per cent.; there were two cases of sarcoma of the spleen.

If we consider the largest spleens only in this series, 63 in number, weighing 600 gm. and upwards, we find the post-mortem diagnosis of cirrhosis of the liver in about 38 per cent. and malaria in another 14 per cent. Of the remainder about 40 per cent. appear to be caused by diseases such as pneumonia, septic infections, typhoid, tuberculosis, etc., which in many instances are only intercurrent affections. The question naturally arises, what are these very large spleens due to and are they suitable cases for splenectomy? It has yet to be decided what proportion of the cases dying from intercurrent diseases are due to pathological processes that would have terminated in cirrhosis of the liver and ascites if life had been prolonged. The comparative rareness of kala-azar in Burma negatives the possibility of this disease being responsible for the production of cirrhosis of the liver as a sequela in that country, and we have already shown in the Bombay series that although malaria is common, cirrhosis is very rare.

We are driven to the conclusion that, if we are to be guided by these groups of post-mortem findings, many of the largest examples of splenomegaly cannot be regarded as post-malarial or post-kala-azar conditions. It is possible that other causes or combinations of causes will be found to be responsible for their production.

The question very naturally arises, why is splenectomy performed so infrequently in India when splenomegaly of the splenic-anaemia type is comparatively common? The undoubted reason is the high mortality of the operation due to the miserable condition of low resistance in which the patients are admitted into hospital. Death is commonly due to shock within a few hours of the operation, or to broncho-pneumonia within a few days. This is well recognized in Egypt where the experience of surgeons of the one definite type of 'Egyptian splenomegaly' is very considerable, and yet with all possible precautions the mortality rate is over 20 per cent. In India and Burma in a very incomplete series of cases of splenectomy for splenomegaly of different types performed at various hospitals during the last ten years, the mortality worked out at 39 per cent. These operations were in some instances performed as a last resource, and the spleens were much enlarged with extensive adhesions. It is obvious that better results can only be obtained by operating at a much earlier stage, or by some different method.

In conclusion it can be stated that the evidence produced here is in favour

of the view that a large class of cases of considerable enlargement of the spleen, sometimes of doubtful aetiology, exists in tropical and sub-tropical countries. Many of these cases progress to a fatal issue in spite of therapeutic measures, and it is believed that some of them could be saved by surgical intervention. More light is needed to be thrown on the subject to facilitate diagnosis, and more experience is needed as regards preliminary treatment to raise the patient's resistance before operation. More exact methods are required, by radiography or otherwise, to determine before operation the extent of adhesion of the spleen to other structures; and improved technique is called for to deal successfully, by the removal or destruction, with a spleen bound down by many adhesions. Ligature of the splenic artery has been carried out with successful results in cases where the spleen cannot be removed; this manoeuvre is worthy of more extensive trial, particularly in the tropics when patients are often too debilitated to stand a more severe operation.

Summary

(i) This paper deals with splenectomy in the tropics, with special reference to tropical splenomegalies.

(ii) A more detailed knowledge of the pathology is needed, and better surgical technique; this can only be obtained by closer collaboration between the pathologist, physician and surgeon.

(iii) Reference is made to the incidence and treatment of ruptured spleens in India, and also to wandering spleen, abscess, cysts, and new growths.

(iv) Three groups of post-mortem cases are described, from Bombay, Calcutta and Rangoon, comprising 1,200 cases of enlarged spleen in 3,308 necropsies; a comparative table is given.

(v) One important class of very large spleens, resistant to treatment, stands out; this may terminate in cirrhosis of the liver and ascites. Some of these are thought to be malarial in origin. Splenectomy is indicated for some of this group.

(vi) Splenectomy has fallen into disfavour in India because of the high mortality rate. It is suggested that good results may be obtained with much less risk by ligature of all the branches of the splenic artery.

SEX HORMONES OF FEMALES

By PROBODH CHANDRA DAS, M.B.

Hony. Visiting Gynaecologist, General Hospital, Howrah, India

THERE has been a very rapid development in the field of research work on the female sex hormones during the last few years. The whole problem is very intricate and necessarily a study of it is of great interest. In the following pages it is my endeavour to give a brief résumé of the researches and work that have been done on the sex hormones of the female.

History of hormonology

Professor A. A. Berthold of Göttingen, in 1849, first demonstrated, by means of experiment, the nature of activity of a true ductless gland. He showed that after castration of cockerels the typical appearances of the castrate are prevented by a reimplantation of the testicle. Claude Bernard is generally credited with having been the first to give expression to the doctrine of internal secretions in 1855. He maintained that, not only the glands by their secretory processes—*sécrétion externe*—by means of which substances are withdrawn from the blood, but that every organ of the body, by a process of *sécrétion interne* whereby it yields its products up to the blood, determines the composition of the blood and can, under certain conditions, modify and even change it.

But the actual introduction of the theory of internal secretions is universally ascribed to Brown-Séquard (1817—94), a native of Mauritius, whose life-work was mainly associated with French Medicine. He was the first to express the idea that all glands, with or without

(Continued from previous column)

majority of these patients have suffered from both kala-azar and malaria, or from malaria alone, but parasites are not found in their peripheral or spleen blood, and specific treatment causes no improvement in their condition. They are often not acutely ill, but the prognosis in such cases is very bad and they remain in a chronic state of ill health for a year or so, and then die of some intercurrent disease.

We have recommended the removal of the spleen in a number of these cases, but we have no records of this having been carried out. The co-operation which Sir Frank advocates must also include that of the patient, and in our experience this has been the main stumbling block.

From two separate sources, both of which we consider unprejudiced and reliable, we have obtained two diagonally opposed opinions on the results of spleen removal in these cases. One physician said that in his experience in all of about a dozen such cases the patient had died of concurrent disease within a few years, though some had shown considerable temporary improvement; this did not reflect on the skill of the surgeons, because the deaths had not occurred immediately. The other, also a physician, said that he had often seen considerable and continued improvement following splenectomy in cases of this nature. Whichever view is accepted it is obvious that, when 'medical' measures have failed, surgery should be given a trial in suitable cases as there is no suggestion that the condition of these patients is worse after the operation, that very thorough investigation of the blood picture should be made prior to the operation, and, what is possibly even more important, that the cases should be followed up very carefully for a number of years, to ascertain the final result of the operation.

In addition to the causes which Sir Frank enumerates it will be recalled that some years ago Mackie (*Indian Med. Gaz.*, 1925, Vol. LX, p. 71) described the occurrence of a familial type of splenomegaly affecting several families in a village in the Bombay Presidency.—EDITOR, *Indian Medical Gazette*.]

ducts, supply to the blood substances which are either useful or essential, and the lack of which may produce pathological signs. The actual date upon which the doctrine of the internal secretions may be said to have been born is June 1, 1889. It was the occasion of that memorable meeting of the Société de Biologie, Paris, when Brown-Séquard, then 72 years of age, described the experiments which in order to prove the hypothesis, he had carried out upon his own person, by the subcutaneous injections of testicular extract.

Our present knowledge of the physiology of the female reproductive organs was initiated by Knauer, who in 1896 showed in experimental animals that transplantation of ovaries prevents the atrophy of the uterus that follows ovarian extirpation. This experiment as well as those of Hallan (1900) and of Simon (1904) proved beyond contention that the ovary is an organ of internal secretion.

What is a hormone?

'Two agents are concerned in the maintenance of the complex activity of the animal organism. In addition to the nervous inter-communication, there is also a "chemical correlation" of the different organs. In accordance with the latter, each organ, each tissue, each cell by means of its specific secretory products, acting through the agency of the blood stream, is capable of exerting a definite influence upon other parts of the body' (Biedl). Bayliss and Starling proposed that the name 'hormone' should be given to those physiological substances which act as 'chemical stimuli' and serve as intermediaries between different parts of the body. The word 'hormone' is derived from a Greek word meaning to awake or to excite. And organs producing such substances are called, 'hormone-producing'. The true hormones have been variously classified according to the manner in which they act. Thus we have formative and protective, growth-producing and growth-retarding, stimulant and inhibitory.

Hormones of the ovary

From the standpoint of endocrine physiology, the ovary must be considered a double gland. The follicular apparatus with its hormone folliculin constitutes the female sex gland proper. The corpus luteum with its hormone progesterin is an accessory gland concerned with pregnancy. Corner has proved conclusively that there are two hormones in the ovary, the one of the follicle he called œstrin, a growth substance having its specific influence during the proliferative stage of menstruation, the other of the corpus luteum he called progesterin, having the specific function of sensitizing the uterine mucosa for nidation of the ovum, and maintaining the raised nutrition of the uterus during pregnancy. These two hormones, œstrin and progesterin, are antagonistic to each other in their effects on the uterus but at the same time they are synergistic, i.e., they produce by combined action an effect which neither could effect when acting alone. Hisaw and Leonard explain the situation thus, 'The function of the follicular hormone seems to be that of putting the uterus in the proper physiological condition so that it can respond to the corpus luteum hormone. Neither of these substances can produce pregestational proliferation in the castrate uterus when given alone; if, however, it is brought into condition typical of œstrus through the injection of the follicular hormone, and is followed immediately by corpus luteum treatment, pregestational proliferation results'. Folliculin injections after impregnation prevent nidation of the ovum and produce abortion, whereas an excess of luteal hormone prolongs the term of gestation and may result, according to Brouha, in intra-uterine death of the foetus due to failure of the onset of labour.

Thus the seeming paradox of the two hormones, working both for and against one another, will be clearly understood by the above facts.

Recent researches show that the corpus luteum contains two hormones, lipamin, which promotes the

growth of the uterus and luteo-lipoid, which checks menstruation. The fully developed corpus luteum regulates the premenstrual changes, the growth of the decidua and of the musculature of the uterus, arrests ovulation in the early months of pregnancy and provides for the undisturbed development of the fertilized and embedded ovum.

The main site of production of the folliculin (œstrin) is in the unruptured Graafian follicle. It is also produced by corpus luteum and placenta. All evidence favours the view that 'atretic follicles' too produce the hormone and that it plays a large rôle in keeping up the trophic nutrition of the genital tract. It is found in amniotic fluid, and in the cord-blood and liver of the foetus. Mazer and Hoffman have found varying quantities of œstrin in the urine of pregnant women as early as the first week after the first missed period. It has been obtained from the blood, urine and bile of males; as well as from sex organs of higher plants, yeasts and in potatoes and other vegetables.

Progesterin (lutin) is elaborated only by the corpus luteum.

Thus, the two clearly defined endocrine activities of the ovary, due to two distinct hormones, occasionally become unbalanced as the result of overactivity of one or the other hormone. The disequilibrium often accounts for sexual disorders such as suppression or abnormality of the sexual cycle and for gestational disorders such as sterility, abortion and abnormal prolongation of the period of gestation. The ovaries differ from other endocrine organs (with the possible exception of the pituitary) in that their functional activities are cyclical. The hormones secreted vary in character and amount with the different phases of sexual activity.

The two hormones of the ovary have been called by a variety of names; that of follicle is known by œstrin, folliculin, female sex hormone, feminin, etc.; the corpus luteum hormone is called lutin, progesterin, beta factor, etc.

Hormones of the anterior lobe of pituitary

According to Zondek the anterior lobe of the pituitary elaborates the following substances:—

Prolan	{	1. Growth hormone.	} Super-ordinated sex hormones.
		2. Prolan A follicle-ripening hormone.	
		3. Prolan B luteinizing hormone.	
		4. Metabolism hormone.	

It will be seen that prolان A and folliculin have properties in common, while prolان B and the corpus luteum hormone, progesterin, are similar; hence prolان A and prolان B are known as superordinated sex hormones.

We know that there exists an inter-relationship between the various glands of internal secretions of the body, but that between the ovary and the anterior lobe of the hypophysis interests us only. The precise way in which the two ovarian hormones and the anterior pituitary hormones act and react upon one another is not yet clear. Just as the gonads are inactive in the absence of the anterior lobe, so the latter organ is incapable of promoting sexual changes in the absence of the gonads.

According to Zondek, prolان A sets off follicle ripening and incites in the theca cells of the follicle = the production of folliculin, which in turn induces the proliferative stage of the endometrium. Prolان B effects the change of the granulosa and theca cells and incites in them the production of progesterin (lutin) which changes the proliferative phase of the endometrium to one of the secretion (premenstrual, pregestational stage).

The placenta and its hormones

The placenta is becoming more and more regarded as a 'ductless gland of pregnancy'. It is both a store-house and a producer of substances necessary for the

nourishment and growth of the foetus. It contains among other things folliculin and an 'anterior lobe hormone'. It has been proved that the placenta actually elaborates folliculin. As to whether the so-called 'anterior lobe hormone' found in the placenta is stored there, its original source being in the hypophysis, or whether the placenta assists the hypophysis in supplying the extra amount required during pregnancy, or whether the placenta alone furnishes it, there exists at the present moment a controversy. Some, notably Phillip, hold that it is the product of the placenta. Zondek on the other hand claims the supremacy of the hypophysis.

Next we may discuss the effect of these researches on the modern conceptions of the onset of puberty, menstruation, parturition and lactation.

Phillip Smith as well as Zondek and Aschheim have demonstrated that the onset of puberty is an anterior lobe pituitary effect. As a result of this pituitary activation, a sudden increase and speed of follicle-ripening take place. Complete maturation of, at least, one follicle occurs with rupture and consequent ovulation, resulting in corpus luteum formation. If no pregnancy has taken place, after a short period, the corpus luteum involutes and regresses, ultimately forming a corpus albicans. If pregnancy has taken place the corpus luteum persists till the end of pregnancy. This fact has, however, merely changed the point of inquiry because no explanation is offered as to why the pituitary at this time suddenly increases its activity. As a passing remark it may be mentioned here that puberty can occur without the appearance of menstruation.

New theories of menstruation

The Graafian follicle as it develops produces by means of its hormone (folliculin) characteristic changes in the endometrium whereby the glands, at first simple tubular, become hypertrophied and tortuous. Near the middle of the menstrual cycle the follicle bursts, ejects the ovum and becomes a corpus luteum. The corpus luteum functions up to the 28th day, inducing by means of its special hormone changes in the endometrial glands by which their structure is altered to that of a secreting organ. The epithelium assumes the beaker form of secreting cells, and the glands exhibit a saw-toothed appearance. These changes become manifest as soon as the corpus luteum is formed. The ovum, if unfertilized, dies supposedly on the 28th day; with the death of the ovum the corpus luteum degenerates and menstruation supervenes. Here also it is not known why the anterior pituitary should produce this follicle-ripening material at a fluctuating rate. For the explanation of this extremely complicated problem Professor Dodds remarks, 'The modern German writers have developed an interesting theory but here a word of warning must be given that it is purely speculative. It is assumed that the anterior lobe pituitary begins to secrete prolan which in turn stimulates the ovary to secrete oestrin. Through the prolonged action of prolan, a corpus luteum is formed and in time this corpus luteum begins to secrete progesterin. The progesterin then reacts on the anterior lobe of the pituitary and reduces the secretion of prolan so that the corpus luteum retrogresses. When the corpus luteum has retrogressed we get an immediate re-establishment of the secretion of prolan, and thus the process goes on. It is not very difficult to think out some very serious arguments against this otherwise highly attractive theory. For example, it will not explain the enormous production of oestrin and prolan during pregnancy when presumably the corpus luteum is also continuing to secrete progesterin'.

Sex hormones and their relation to pregnancy and parturition

If after the extrusion the ovum becomes fertilized, the collapse of the corpus luteum and endometrium does not take place. The corpus luteum grows larger

and continues its hormonal influence on the endometrium. The endometrium persists as a secreting organ, becoming the decidua and retaining as such the characteristics of its premenstrual stage in a more pronounced form. Aschheim and Zondek found that in early pregnancy there is a relative excess of the anterior lobe pituitary hormones over the ovarian,

Figure showing the inter-relationship between the anterior pituitary and ovary and also correlation between ovarian and endometrial phases (after Zondek). Prolan A incites the ripening follicle to the production of folliculin, which in turn acts on the endometrium producing proliferative changes. (That corpus luteum also produces a small amount of folliculin is indicated by dotted lines.) Prolan B stimulates the corpus luteum to the production of progesterin which changes the proliferative stage of the endometrium to premenstrual stage. Under the influence of the ovarian hormones the endometrial glands, at first simple tubular in the resting phase, become saw-toothed and tortuous in the premenstrual stage.

whereas this position is reversed in the later months. It has been suggested that this change in the hormonal balance is probably concerned with the onset of labour. Jeffcoate has recently shown that if this upset occurs in the early stages of pregnancy then expulsive contractions of the uterus follow. Mention may be made here of the fact that a synergistic effect of folliculin and oxytocin, the oxytocic principle of the posterior pituitary, in stimulating the uterine contractions has been demonstrated and it has also been shown that administration of progesterin can make the uterus insensitive to this combination. Knaus has proved that there exists an antagonism between the internal secretion of the posterior lobe of the pituitary and that of the corpus luteum. It follows from this work that the action of the posterior lobe secretion in causing uterine

contraction is inhibited during pregnancy. Consequently, as postulated by Marshall, the regression of the corpus luteum is one of the main factors in bringing about parturition. Smith and Watkins remark, 'Just before delivery the outstanding endocrine situation is this:—folliculin has reached its highest level, the luteinizing hormone has decreased, and the corpus luteum apparently has become insignificant. With the disintegration of the corpus luteum, oxytocin acts on the uterus already sensitized by the œstrin and brings on labour'. It appears that oxytocin exerts its influence on the uterus only when it is first sensitized by the œstrin. Parturition normally occurs at what would have been a menstrual period if pregnancy had not supervened.

The explanation of post-maturity probably is that the progestin which normally holds œstrin in check is still being secreted in large quantities owing to non-disintegration of the corpus luteum.

Remarking on the new theories regarding lactation, Graves says, 'In some, it has been demonstrated that the proliferative and lactational changes of mammary glands during pregnancy and following parturition are due not to a follicular or corpus luteum hormone as formerly supposed, but to the direct action of the anterior lobe of the pituitary. Whether or not the effect is due to a special hormone of lactation or whether it is identical with one of the two proved hormones of the anterior lobe hypophysis has not been determined'.

Applied sex hormonology

Out of the researches have evolved various tests with modifications for the diagnosis of pregnancy. Of these, the one invented by Aschheim and Zondek is used universally with persistently uniform results. This test depends upon the presence of prolan B, the lutealizing hormone of the anterior lobe of the pituitary in the urine of pregnant women, which when injected produces characteristic changes in the ovaries of laboratory animals.

But substitution therapy has hopelessly failed to keep pace with the brilliant physiological discoveries in sex hormonology. In fact ovarian extracts have been used medicinally, for all kinds of menstrual disorders for a long time though without any success. It is only in very recent years that any attempt has been made to treat ovarian therapy scientifically. On the clinical uses of the ovarian hormones Marshall remarks, 'The use of œstrin is only indicated in cases where there is evidence of a natural deficiency of this substance as with certain types of amenorrhœa or after ovarian extirpation, and, much more problematically, at the time of the menopause. In a similar way the use of progestin may only at present be reasonably justified in cases where there is evidence of a deficiency of the hormone, if indeed this ever occurs. Such deficiency may conceivably be an occasional cause of abortion, but there is no direct proof of this happening'.

There are various commercial products of ovarian hormones in the market produced by commercial concerns for therapeutic uses, a list of which is appended below.

Preparations containing œstrin

Agomensin (Ciba), Amniotin (Squibb), Estrogen (Parke, Davis), Glovarian Pills (Schiefflin), Menformon (Degewop), Progynon (Schering), Theelin (Parke, Davis), Varium (Burroughs Wellcome).

Preparations containing progestin

Lipo-lutin (Parke, Davis), Lutein tablets (Hynson and Westcott), Sistomensin (Ciba).

The clinical results of these extracts have not been very promising and investigators all over the world have failed to obtain uniformly good results. This is due to the fact that effective sex hormone therapy depends on many factors among which the following are the most important, viz:—(a) proper biological assay and standardisation, (b) purity, (c) mode of administration. If the material is very active then it

(Continued at foot of next column)

ACUTE PAINFUL CONDITIONS OF THE EAR

By K. E. MADAN, M.D., D.O.M.S.

Lahore

THE practical points in the differential diagnosis of the various acute painful conditions of the ear are not clearly mentioned in textbooks on the subject, and hence the following lines are meant to point out very briefly the important distinguishing features in their diagnosis. It is best to divide them into acute painful conditions of the external, middle and internal ear, and to referred pain in the region of the ear.

The diagnosis of acute painful external ear conditions, e.g., erysipelas, herpes, eczema, impetigo contagiosa, active hyperæmia, and other traumatic conditions is obvious or can be easily made out, so they will not be dealt with here. The acute painful conditions which affect the external auditory canal are (1) furunculosis, (2) inflammation, septic, diphtheritic, or pseudo-diphtheritic (croupous), (3) foreign bodies. The differential diagnosis of these and all other conditions

(Continued from previous column)

must be given in a series of divided doses by subcutaneous injections. When administered orally, the hormones become inert. The water-soluble forms of the hormones undergo rapid deterioration with loss of potency. Also sometimes severe local reactions develop at the site of injection. Finally, the prices of these extracts are practically prohibitive.

is made by the history, inspection, particularly with Siegle's pneumatic speculum, hearing tests, microscopic examination of the discharge, x-rays, and examination of neighbouring parts and comparison with the other ear.

As pain is a common symptom to all the acute conditions discussed here, careful attention should be paid in their differential diagnosis to note all the points regarding this important symptom of pain, such as its nature, degree, duration, location, extent, mode of onset, whether it is nocturnal or diurnal or continuous and which more severe in degree than the other, and whether aggravated by manipulations of the auricle, movements of the jaw, etc.

In *furunculosis* there is severe throbbing pain, and great tenderness. The pain extends to that whole side of the head and is aggravated by eating, due to movements of the jaw, and by even gentle manipulation of the auricle. Deafness is not complained of until the furuncle becomes big enough to close the canal.

In *acute diffuse inflammation*, there is early and intense pain, with deafness and tinnitus. The swelling of the canal does not allow a view of the drum-head. Over spots where the inflammation is greatest, there is some excoriation of the skin and a slight watery discharge.

In *diphtheria of the external auditory canal*, there is formation of a moist layer of pseudo-membrane which when pulled out causes bleeding. The Klebs-Loeffler bacilli are present in these membranes. In addition to pain, marked swelling of the meatus, deafness, and tinnitus, there are enlarged and tender lymphatic glands at the angle of the jaw with fever.

In *croupous otitis externa*, though a pseudo-membrane is present and when peeled off bleeds, the germs found are streptococci and staphylococci; the discharge is purulent and there is hardly any swelling of the neck glands.

Foreign bodies in most cases do not cause acute pain. If an insect is inside the ear, it ceases to give trouble as soon as it is killed.

Acute inflammation of the canal may also be produced by *otomycosis* which is due to fungus infection; although it is comparatively rare, it is a very troublesome condition. A moist, pasty, dirty grey, coloured mass occupies the entire canal, and pain, itching and stinging are complained of. This accumulated mass causes deafness. Microscopic examination shows the presence of *Aspergillus glaucus* or *niger*.

The tympanic membrane or drum-head may get acutely inflamed, a condition known as *acute primary myringitis*, due to some trauma, instrumentation, or action of irritating drugs or cold wind. In severe cases there are all the signs of acute inflammation, viz, pain, heat, redness, tenderness, swelling and loss of function resulting in a little deafness. Vesicles or even abscesses may develop in the dermal layer. Movements of the jaw, pressure in front of the tragus, or traction upon the auricle, increase the pain.

In *acute catarrhal otitis media*, the handle of the malleus is red with dilated vessels running across the drum-head, and the membrane is not quite as glossy as normal. When there is some fluid in the tympanum, a thin curved line is noticeable which represents the upper limit of the fluid. It is common to see air bells which shine and move on using the Siegle's pneumatic speculum. If no pultization air bells appear through the membrane, it shows the presence of fluid in the tympanum. In this condition also there is increased pain on jaw movements, pressure over the tragus, or outward traction on the auricle as in myringitis; but here in addition there is fullness and pain in the ear, deafness, tinnitus, and crackling sensations in the ear and vertigo in proportion to the exudate in the tympanum. Hearing tests show that there is deafness for aerial conduction, the lower tones being unheard but the medium and higher ones are heard. Rinnie's test is negative, and Weber's lateralization test refers

(Continued at foot of next column)

THE MEDICAL PROFESSION AND THE BIRTH CONTROL MOVEMENT

By A. P. PILLAY, O.B.E., M.B., B.S.

Director, the Eugenic Clinic, Bombay

THE health of individuals and communities interests no class of persons more than the members of the medical profession and yet very few of us realise the great importance of birth control to these two subjects. Birth control, however, is primarily a problem of the woman and the two chief factors that greatly concern her are her own health and the health of her children. It will be conceded by every medical man that in certain physical and mental ailments, the woman should not conceive. If she does, she dies or her complaint is aggravated and the progeny is born debilitated or diseased. The maternity mortality rate in India is very high, ranging in places from 3 to 53 per thousand live births. The contention is not that all these deaths are due to the cause mentioned above but that it is a very important factor in a country where marriages are universal and the maternity service is notoriously crude. Add to this the thousands of mothers in India who are always ailing. It will also be conceded by the medical profession that adequate spacing of childbirths is essential in debilitated women in their own and in their children's interests. The following tables prepared by the Children's Bureau of the United States Department of Labour are interesting in this connection:—

Interval between births.			Infant mortality rate.
1 year	147
2 years	98
3 years	86
4 years	85

(Continued from previous column)

the sound to the affected side. Bone conduction is intensified. The patient hears his own voice sounds abnormally loudly in his affected ear, and those of others abnormally low as if coming from a great distance.

In *acute suppurative otitis media*, the attack is ushered in by shooting pain in the ear and side of the head, with temperature up to 103°F., deafness and tinnitus. The otoscopic appearances in the beginning are that the membrane becomes red and loses its transparency, and is bulged outward; the malleus handle may not be seen, but a dimple only may be found in its place; when perforation occurs, pain is relieved, and there is pus in the meatus and when this is wiped out, a minute perforation is seen; diagnosis is easier with Siegle's speculum; after cleaning the pus, if the hearing tests are normal, there is no otitis media, but some other condition like furunculosis or otalgia, in which carious or painful tender teeth, particularly molars, cause referred pain to the ear with tinnitus.

In *acute mastoiditis*, the first symptom is intense pain over the mastoid and the whole side of the head. The patient has a very anxious expression and has no sleep or inclination to take food. Fever, mastoid tenderness, sudden cessation of discharge from the meatus, swelling and congestion of the upper posterior part of the meatus are very significant of acute mastoiditis.

It should be kept in mind that the pain complained of in the middle ear, mastoid, and cerebral affections has the following distinguishing characters: in suppurative otitis media, pain is deep-seated in the ear; in mastoiditis, pain is behind the ear; in cerebral affections there is headache or the pain is in the head, and nocturnal pain is more severe; in the early stages of intracranial complications, when there is irritation of the dura, the pain is usually situated in the temporal region directly above the ear.

TABLE B

Number of children in the family.	Infant mortality rate.
4 and less	118
6 and more	267
7 and more	280
8 and more	291
9 and more	303

TABLE C

Order of birth.	Infant mortality rate.
1st and 2nd born	138.3
3rd and 4th born	143.2
5th and 6th born	177.0
7th and 8th born	181.5
9th and later born	201.1

TABLE D
(Indian figures)

	Infant mortality rate.	Percentage of stillbirths to live births.	Children alive per 1,000 pregnancies.
5 pregnancies and under.	226.3	12.5	633.7
6 pregnancies and over.	272.2	20.9	504.4

TABLE E

Age of mother.	Infant mortality rate.
Under 18	160.3
18—19	128.9
20—24	109.5
25—29	101.4
30—34	101.7
35—39	126.5
40—44	131.3
45 and over	250.0

The income of the family, it will be admitted, has a great bearing on infant mortality rate and the health of surviving children. The following table, again prepared by the Children's Bureau of the United States Department of Labour, is instructive:—

TABLE F

Earnings of father in dollars.	Infant mortality rate.
Under 400	170
450—549	130
550—649	120
650—849	110
850—1,049	90
1,050—1,249	70
1,250 and over	60

The infant mortality rate and the health of surviving children will thus be seen to be mainly dependent on:

- (1) The mother's health.
- (2) The child's possible heritage.
- (3) The father's earning capacity.
- (4) Child spacing and the number of children in the family.
- (5) The age of the mother.

Apart from the purely medical aspects of the question there are also certain factors coming under public health. Among these might be mentioned the following: birth control will lessen prostitution by promoting early and happy marriages and by allowing the husband to have all the sex life he needs at home without fear of injuring the health of his wife. It will also indirectly tend to reduce the incidence of venereal diseases. Overpopulation and its consequent evils like child labour and a low standard of living will be checked. This will leave the community free to raise its standard of health and living.

For controlling births and for child spacing there are at present only one unapproved and two approved methods. These are abortion, continence and birth control. Abortion no medical man worth the name will advise or practise, and yet the number of abortions that

are carried out or attempted every year even among the married, will run into lakhs. Any chemist, nurse or gynaecologist will confirm this statement from the number of entreaties they receive for prescriptions 'to regulate menstruation'. We are thus left with only two permissible alternatives, self control and birth control. To the medical profession there is nothing new in the statement that the sexual appetite, after hunger, is the most dominating and insistent instinct of life, though society, ignorant of the overwhelming importance of the subject, may clamour for its suppression. Self control implies the repression of a natural and necessary instinct and it is a psychological truism that repression of such an instinct is more harmful than its expression. Clinical data bear out this statement. Young and normal couples cannot long carry out this repression without mental, physical and moral deterioration. To those who can practise self control, the teaching of contraceptive methods is certainly unnecessary. My opinion is that most, if not all, physicians favour birth control and many practise it themselves. Why do they not then prescribe it in their practice? Is it lack of courage or lack of humanity or lack of knowledge of the subject? The reasons appear to be one or other of the following:—

- (1) Religious prejudice or conscientious objections of the doctors or their superiors.
- (2) Stigma of indecency.
- (3) Fear of its being misused.
- (4) Ignorance of the methods of birth control.

Science was once greatly dominated by religion but now it realises its power and value, just as it realises its limitations. This is why in treating and advising the sick, it does not allow religion to interfere. Advice on contraceptive methods is a form of treatment and why should religion be allowed to interfere in this case alone? Religion can lay down moral principles regulating the behaviour of individuals towards one another but it cannot meddle in the private affairs of persons. As regards the stigma of indecency there is none attached to the subject of birth control, or if there is any at all, it belongs to the mind of people who consider it indecent. Admittedly there is a possibility of birth control advice being misused, but then is it better that the world should go on being scourged with venereal diseases and with abortions and the sacrifice of countless mothers and infants than that it should be freed from these horrors at the expense *perhaps* of increased illicit sexual relations? To my mind, the chief reason why doctors do not prescribe contraceptive methods in their practice is their ignorance of the subject. They get their information not from specialists or from scientific treatises but from their friends who are often laymen, or from chemists' advertisements. This makes them doubt the reliability and harmlessness of the methods they know and hence they hesitate to prescribe them. Professor Julian Huxley says:—

'Our children will look back with incredulity upon an age in which doctors could warn women that they must on no account become pregnant again and yet withhold all advice as to how this could be accomplished, even when implored to give it'.

It is unprofessional, nay inhuman, to deny such advice to women who actually need it.

Sir Clifford Allbutt, when made President of the British Medical Association several years ago, said: 'Every righteous physician regards his practice as a social service, a means not only of bodily but also of social reconstruction and of moral and intellectual health'. The physician is hindered from this ideal by limitations as regards birth control which prevent him from acting to his fullest capacity as the adviser and guide in the processes of social reconstructions. This mentality is the cause of the subject of contraception being still in its infant stage and the rapid spread of unreliable and even harmful methods among the people. The medical profession can certainly be accused of adopting an unprofessional attitude towards this very necessary, humane and scientific subject.

Medical News

THE CALCUTTA HOSPITAL NURSES' INSTITUTION

(From *The Statesman*, 1st November, 1932)

NURSING PROSPECTS

A RESOLUTION published last week in the *Calcutta Gazette* states that in view of the burden thrown on provincial revenues by the cost of providing nurses in the general hospitals of Calcutta, the Government of Bengal have decided that the question in all its aspects should be investigated by a committee representative of the various interests concerned. The committee is to consider whether any economies can be effected by obtaining for their hospitals a supply of well-trained and competent nurses, male and female, from new local sources, without any lowering of the present standard, which looks uncommonly as if the Government, having given up the problem in despair, expect Colonel Stewart and his colleagues to square the circle for them.

There are in Calcutta, among other hospitals, the Presidency General, Medical College, Eden Maternity, Prince of Wales, Ezra, Eye, as well as the Carmichael Hospital for Tropical Diseases. All except the first-named belong to what may be termed the Medical College group, and all are Government hospitals. Under a rather unusual state of affairs the nursing staff for these hospitals are recruited, trained, and provided, free of charge, by an outside body, the Calcutta Hospital Nurses' Institution, which bears the whole cost of the food, clothing, pay, and servants of the nurses. Now these services cost money, and the necessary money is proving ever more difficult to find; hence the appointment of Colonel Stewart's committee. For their revenue the Institution depend principally on a Government grant; a small grant from the Corporation; donations from the charitably-minded public and firms of Calcutta, and to a limited extent only—a little over half a lakh of rupees in 1931—on fees from the hospitals. Expenditure in the year 1931 showed a trifling increase over the previous year, but did stand at Rs. 4,23,498 compared to Rs. 3,00,309 in 1921. Presumably the Institution's retort to the fact that expenditure between 1921 and 1931 rose by a lakh and a quarter of rupees would be that in the latter year the number of nurses maintained by the Institution, excluding superintending staff, stood at 236, compared with 178 in 1921.

On the other hand the Institution's revenue for the year 1931 showed a deplorable fall of Rs. 40,000. With two trifling exceptions every revenue head showed a fall, donations and subscriptions alone being Rs. 18,061 down on the year before. This is one tragic reflection of the world-wide depression, nor is it any comfort to learn that during the first half of the current year donations and subscriptions were Rs. 16,000 lower than during the corresponding period last year. Almost entirely because of this serious drop in revenue the Institution showed during 1931 a deficit of Rs. 42,928. In consequence new recruitment of nurses was closed as from December last, a step which was inevitable but which if prolonged cannot but result in heavy and increasing strain on the nursing staff and have deplorable results on the whole outlook for nursing in Bengal.

Is there any means for raising fresh revenues? Private donations and subscriptions, which stood at Rs. 1,54,366 in 1930, and Rs. 1,36,304 in 1931, constitute the Institution's principal source of income. Next come the Government of Bengal, who for some years have been contributing Rs. 1,25,000 annually, plus, from time to time, emergency grants. (Rs. 88,000 has been promised for the current financial year, for instance.) Private subscriptions not being likely, so far as one can tell, to show any increase for some considerable time to come, the Government remain the sole hope. But

Government complain that their revenue too has been dropping seriously, while demands on their resources are continually growing. This is the official reply to suggestions that Government's annual contribution should be increased to Rs. 1½ lakhs. Unless Government can come to the rescue a serious situation is inevitable. Estimates are notoriously difficult to make at the present juncture, but the Institution's income for 1932 is estimated at Rs. 80,000 less than it was in 1931, and the income for 1931 was Rs. 42,000 short of expenditure. As is the case in Bombay, several wards in the hospitals may have to be closed.

No fair-minded man can deny the difficulties facing the Government at the present time. Government have perhaps been slow to appreciate that certain hospitals are Government hospitals, and that however splendidly a hospital may be equipped with the latest technical apparatus the apparatus might just as well not be there if the nursing staff is inadequate, a state of affairs certain to prevail in the near future if the matter is not faced courageously as soon as possible. Government have also to consider their responsibilities to the taxpayer, European and Indian. It would be affectation to pretend that the nursing profession anywhere in India is regarded as it should be. In cases of serious illness the nurse may be more important than the doctor, but our correspondence columns during the summer showed a deep-seated reluctance on the part of the up-country and Calcutta public to appreciate this truism, as well as a strong resentment against any proposal that the standard fees should be raised. Some correspondents thought Rs. 10 per day or night ample remuneration in 'these hard times', forgetting that on the average nurses are occupied at most half the month, and that on this scale of ten rupees, even if a nurse were occupied the whole month, she would earn only Rs. 300. If that is the European and Anglo-Indian view, the Indian does not regard nursing as at all a profession in which to put his daughter. In fact, he very definitely regards it as something she should avoid. Until the public in India realize that for sick nursing, nurses are the most indispensable necessity of all, they must be prepared to see the health of the community suffer.

MEDICAL COLLEGE, CALCUTTA

DR. CHANDRA'S SCHOLARSHIP IN MATERIA MEDICA AND THERAPEUTICS

THE above scholarship of the value of Rs. 361-8-0 will be awarded during the session to the best candidate who complies with the terms of entrance for this scholarship, which are as follows:—

- (1) The scholarship is open to:—
 - (a) All senior students of the Medical College, Calcutta.
 - (b) Students at present studying at any medical college in India or Europe who have at any time been senior students at the Medical College, Calcutta.
 - (c) A graduate or licentiate in medicine who may have obtained either in Europe or in India a medical diploma or degree entitling him to practise medicine, provided that such graduate or licentiate at some time received a portion of his professional education in the Medical College, Calcutta.
- (2) Certificates to the effect that the candidate fulfils the above requirements, together with a certificate of good moral character, signed by a person of respectability, should be submitted to the Principal, Medical College, Calcutta, on or before 15th February, 1933.
- (3) Candidates will write an essay on the pharmacological action and therapeutic uses of *Rauwolfia serpentina* (dhan barua or dhan

marua), and submit this to the Professor of Pharmacology, Medical College, Calcutta, by 15th March, 1933.

Note.—Personal attendance is not necessary.

Preference will be given to the candidate whose thesis bears evidence of original investigation on the subject.

(The above is a résumé of the terms of the scholarship; for further details application should be made to the Principal, Medical College Hospital, Calcutta.—*Editor, I. M. G.*)

FIFTY YEARS AGO

(From the Editorial, *Indian Medical Gazette*, January 1883)

If future observation endows the germ theory with more substantiality than it now possesses, it will command very special attention and interest in the country, where so much sickness and mortality are due to

maladies which have repeatedly been attributed to microphytes, e.g., cholera, fever, leprosy, elephantiasis, syphilis and phthisis. Our knowledge of these diseases has not undergone any appreciable addition during the year, and it seems as if the mere study of the phenomena of these affections were insufficient to guide practice, whether preventive or remedial, and that until the intimate and immediate cause of them has been discovered, we must remain content to grope in the dark. It is remarkable and somewhat disheartening how little aid is derived from empiricism, and the history of medicine shows that this has ever been the case. If disease germs were indisputably demonstrated and their natural history thoroughly worked out, power would result from that knowledge, such as all the superficial and empirical labours of ages have failed to establish. One fact, however, of immense practical importance is yearly becoming more prominent, and that is, that, whatever the intimate cause of so-called zymotic disease may be, its dependence on sanitary shortcomings and prevention by sanitary reforms is indisputable.

Current Topics

Treatment of Hypertony

By I. HARRIS, M.D.

Königsberg

(Abstracted from the *Lancet*, 10th September, 1932, p. 560)

RECENTLY we have shown that the administration of certain drugs for the purpose of reducing pressure in cases of hypertony results in a disturbance of the equilibrium of the different blood constituents. Patients with hypertony whose pressure was reduced artificially showed an increase of blood-urea and non-protein nitrogen; the water-excretion function was depressed, the alkali reserve of the blood diminished, and the cardiac reserve power lessened. These facts suggest that the indiscriminate use of pressure-reducing drugs is extremely undesirable. In this paper an attempt is made to study certain methods of treatment of hypertony in relation to their action on blood chemistry.

At the outset it is necessary to differentiate between methods of treating hypertony whose object is simply the reduction of pressure without regard to ætiological factors, and methods whose aim is to reduce pressure by treating the causal factor. The first must be of doubtful value, the second can do nothing but good.

The patients were kept in bed. During the first week no treatment was given. During the second week Collosol sulphur was injected, 3 c.cm. daily. During the third week six pints of water were given daily. The patients were kept on a standard diet all the time. In other cases the procedure was altered. In the first week the patient had no treatment; in the second week he was put on salt- and sugar-free diet; in the third week a diet consisting mainly of carbohydrate, and in the fourth week a pure meat diet was given.

WATER

I know of no method of reducing blood pressure which is uniformly efficacious in all cases. Indeed, considering the various ætiological factors of hypertony, no uniformity can be expected. The drinking of large quantities of water effects a striking reduction in the blood pressure in many cases. I have used this method with good effect in cases of high blood pressure with a high degree of viscosity for the purpose of lowering the latter. At that particular time it was not clear to us why the action of water should have been what it was. I am now in a better position, I believe, to conjecture the reason of its beneficial action. I found

that in cases under sulphur treatment, *pari passu* with the reduction of pressure, there was an accumulation of deleterious substances in the blood. The same phenomenon was observed when the pressure fell simply as the result of heart failure. This suggests that high pressure in cases of hypertony is needed for the purpose of maintaining a normal chemistry balance in the blood. On the other hand, cases under treatment with water, although the blood pressure was definitely reduced, showed a normal blood chemistry. The beneficial effect of large doses of water is probably due to the fact that it enables the kidney to excrete urea and allied substances more easily. In this way a normal blood chemistry balance is maintained and there is no longer a necessity for a compensatory hypertony.

It has been contended that large quantities of water increase the strain on the heart by increasing the blood volume. It is, however, obvious that a treatment which reduces pressure and blood viscosity must also diminish the cardiac strain. Moreover, I have been able to show that there is no hydraemia after the imbibition of large quantities of fluid. Therefore there cannot be an increased blood volume under this treatment. So far as the kidney is concerned, the drinking of large quantities of fluid is all to the good. It has long been established that the work which the kidney performs in passing concentrated urine is far greater than when the urinary output is diluted.

SALT- AND SUGAR-FREE AND PROTEIN DIET

A salt- and sugar-free diet reduces and a protein diet increases the blood pressure. Broadly it may be stated that in hypertony the blood pressure stands in an inverse ratio to the non-protein nitrogen level in blood. It is true, as we have seen, that after the imbibition of large quantities of water both the pressure and the non-protein nitrogen (N.P.N.) tend to be lower, but in this instance the action of the water is what it is because it apparently does away with a causal factor of hypertony (*viz.* increased blood viscosity). The blood-urea is somewhat increased under the salt- and sugar-free diet and somewhat diminished under meat diet, although urea is an end-product of protein. It is possible that a low blood-urea after meat may be explained by the diuretic properties of this substance. The increase of blood-urea after a salt-free diet is by no means so pronounced and constant as it is under conditions where pressure-reducing drugs are given. It is possible the increase has something to do with the

this finding, it is generally considered that the endometrial change is associated with subnormal ovarian function. However, the complete removal of the ovaries does not lead to any similar condition, and J. B. Collip (1932) has found that the fluid from such follicular cysts in cases of this type of irregular uterine bleeding may contain up to 25 rat units of œstrin per c.cm. This suggests that there is a secretion of œstrin from the ovaries which is disproportionately great, whether absolutely or relatively to the reduced activity of luteal tissue which may be inferred from the appearance of the ovaries. With regard to the suggestion made by Shaw, that the ovary produces some abnormal toxic substance, it may be stated that similar suggestions have been made from time to time for other organs of internal secretion, but in every case the view that disturbances are due to excessive or deficient formation of the normal hormone has prevailed.

EFFECT OF THE HORMONE ON BLEEDING

Animal experiments show that excessive doses of œstrin not only affect the production of monophasic cycles, but in continued administration may eliminate the cycles. Excess œstrin affects the entire human organism. As regards the uterus the effect is not limited to the endometrium, but affects the myometrium as well, and herein lies an important consideration. The continued administration of moderate doses of the anterior pituitary-like hormone (A. P. L.) in immature female rats leads to the precocious appearance of normal œstral cycles, while the ovaries rapidly attain the size and appearance of those of normal adults. There is, therefore, reason to suppose that this substance might directly, or through the anterior pituitary, correct the changes observed in the ovaries in metropathia hæmorrhagica, and lead to the appearance of normal balanced ovarian function and the recovery of normal uterine structure and function. This expectation was realised in many cases of varied types.

Preparations of different strengths were used, but the dosage was so adjusted that the patient received at least 40 day-rat units per injection. Our best results were obtained by an injection every day for seven days, then every second day until the patient had passed through two menstrual cycles. When the menstrual flow became of normal duration and proportion treatment was discontinued. A high percentage of cases in all groups responded. In all groups there were some instances of recurrences of metrorrhagia or metrorrhagia, but upon reinstitution of the therapy the cases responded with comparatively few injections. Group D, however, proved disappointingly refractory.

In typical cases of so-called metropathia hæmorrhagica, the institution of A. P. L. treatment did not cause any immediate cessation of bleeding; indeed, while hæmorrhage commonly became less copious, there was no striking change for eight to ten days, and then the bleeding became very profuse, usually worse in the morning, with sharp 'spurts' throughout the day. This exacerbation, however, gradually subsided, and the bleeding practically disappeared except for slight metrorrhagia, for from four to five days' duration, or lasting into the next cycle. The majority of cases, when treatment was continued, manifested a menstrual period on the twenty-eighth day after the first exacerbation (which is regarded as an epoch superimposed on the background of more or less continuous hæmorrhage), and at this period the hæmorrhage was usually greater than a normal flow in duration and amount, clots and large mucosal fragments were passed, accompanied by considerable pain. Usually the treatment was discontinued at this point; if, however, the uterus remained large, and no pain was experienced, the treatment was continued; it was assumed with some reason that the bleeding of metropathia, which is characteristically painless, was not overcome and that the myometrium had not returned to normal. It may be that several menstrual cycles must elapse before the endometrial over-growths are completely shed, since Whitehouse has

shown that the uterine mucosa is not completely nor uniformly shed, even in normal menstruation. On the other hand, in cases which were curetted prior to the institution of therapy the result was considerably hastened. Once cycles of normal interval and proportion were established, they continued normally thenceforward, and in all cases which responded the uterus too returned to normal proportions. This maintenance of normal rhythm has been followed in some cases for over two years. There were, of course, exceptions to this typical history—for example, in women near the menopause, where the cessation of hæmorrhage is followed by amenorrhœa. It is of interest to note that the vasomotor disturbances of the menopausal syndrome did not appear in such cases.

In patients with continuous uterine bleeding dating from puberty the gross response was satisfactory, no matter how long the hæmorrhage had continued, though after one or two cycles the normal rhythm was not perfectly established, being punctuated with periods of amenorrhœa lasting up to three months. Only very occasionally did the symptoms recur. It is worth noting that over 10 per cent. of the cases in this entire series had at some time or another previously been treated with radium or x-rays, with only temporary improvement.

In cases of post-partum metrorrhagia the results were particularly good; there were ten cases treated, and all responded. Excessive menstruation following abortion responded similarly.

When pelvic inflammatory disease was the cause of metrorrhagia or menorrhagia the symptoms were aggravated by this method of treatment.

In cases of polymenorrhœa with flow of normal character, but recurring at irregular short intervals, it was sometimes possible to increase these intervals by three or four days; the previous condition, however, recurred when treatment was discontinued.

OTHER USES OF THE HORMONE

May I again emphasise the need of an outlook that extends beyond the endometrium and the study of mere local changes? The entire human organism is influenced by ovarian function. While the endometrium is a tissue easily accessible to study, the pattern of which alters from day to day, there are changes of a general biological character which may give rise to clinical symptoms, though they are not evident in the endometrial architecture.

In this connection clinical trial of A. P. L. extract was extended to other conditions. Thirty cases were treated for menopausal symptoms and 24 responded. The improvement was marked even when a considerable time had elapsed since the last menstruation. In six of these cases in which periods had ceased for various lengths of time up to one year, menstruation reappeared in from eight to ten days.

In cases with mastalgia, or so-called chronic mastitis, particularly those associated with abnormal menstrual cycles, not only was the pain relieved, but the small pea-like nodules in the breast disappeared. Let me add here that the normal mammary gland was never affected even in prolonged administration of A. P. L., nor was the post-partum breast in any way altered.

A form of urticaria associated with subnormal ovarian function and refractory to all other forms of medication disappeared with the administration of this hormone. Vomiting of early pregnancy was not improved, though it is worthy of note that in none of the cases treated was there any tendency to abortion. Cases of sterility, in most instances associated with polymenorrhœa, did not become pregnant, though two cases suffering from metrorrhagia became pregnant while being treated, and one other with a similar condition became pregnant immediately after cycles were established.

Dysmenorrhœa was intensified. It has previously been pointed out that in the treatment of menorrhagia and metrorrhagia the appearance of pain frequently

marked the beginning of improvement. Intermenstrual pain (Mittelschmerz) became more severe under treatment.

In cases with normal cycles no change either in the amount of haemorrhage or the duration of the interval was observed, even when the injections were continued for months.

A typical menstrual period occurred in ten cases of secondary amenorrhoea in from 10 to 14 days after therapy was instituted. No success was obtained in similarly treating primary amenorrhoea. The preparation of anterior pituitary-like hormone used by us did not cause any local symptoms or alteration in blood pressure levels or give rise to systemic reaction.

It is generally held that the corpus luteum is essential for normal menstrual cycles, but I believe that this dogma must be modified, as pointed out in a previous communication (Campbell and Collip, 1930). Moreover, Corner and Hartman have shown that the corpora lutea are not necessarily present in ovaries showing cyclic activity as manifested by menstruation. Ovarian function in the human may, therefore, be largely appraised by the regularity, amplitude, and duration of the menstrual epochs as well as by general well-being.

IMPRESSIONS

(1) There are several types of irregular uterine bleeding which may be distinguished by their menstrual histories. In selecting cases for treatment, correct diagnosis is essential; the organs in the pelvis must be palpably normal, and the presence of neoplasms of the uterus must be excluded. (2) Menorrhagia and metrorrhagia due to inflammatory diseases are aggravated. (3) Metropathia haemorrhagica responds particularly well. Pain is taken to signify that the musculature has returned to normal tone, and that the hyperplastic endometrium is being rapidly expelled. (4) Response is not so consistent in metrorrhagia of puberty, and treatment is followed by periods of amenorrhoea. (5) Menopausal symptoms are alleviated. (6) Mastalgia, if accompanied by disturbed menstrual cycles, frequently subsides. (7) No permanent improvement is noted in simple polymenorrhoea. The symptoms of dysmenorrhoea are intensified. (8) There is no effect in pregnancy, and no effect upon normal menstrual cycles as regards interval, amplitude, or duration; no local or constitutional symptoms are observed. (9) It is considered that the effect of the anterior pituitary-like hormone is to cause the ovary to resume a complete and balanced endocrine activity, in place of one that is unbalanced and incomplete.

The extract used in these studies was prepared in the Bio-Chemical Laboratory of McGill University by Professor J. B. Collip.

The End-Results of the Tonsil and Adenoid Operation in Childhood and Adolescence

By J. ALISON GLOVER, O.B.E., M.D., M.R.C.P., D.P.H.
and

JOYCE WILSON, M.B.

(Abstracted from the *British Medical Journal*,
10th September, 1932, p. 511)

1. THE rising flood of tonsillectomy has been shown in the immense and rapid increase in the numbers of operations annually performed, and by the astonishing fact that more than half the most carefully nurtured children in Britain are now subjected to it, whereas forty years ago none of their parents underwent the operation. Whilst the incidence of tonsillitis is at least as high amongst the poor as amongst the well-to-do, the children of the latter have an incidence of tonsillectomy at least four times as high.

2. A review of the literature suggests that, with the single exception of diphtheria, the incidence of the

ordinary infectious diseases is unaffected by tonsillectomy; that while the incidence of recurrent sore throats is perhaps somewhat diminished, that of frequent colds is unaltered, or perhaps slightly increased. The incidence of otitis and mastoid disease is the same, or perhaps slightly increased upon the tonsillectomized, while their liability to bronchitis and pneumonia is also probably slightly increased.

3. The evidence with regard to the prophylactic and therapeutic end-results of tonsillectomy on acute rheumatism, chorea, and carditis is distressingly confusing. There is no sufficient case for the routine removal of apparently healthy tonsils in a rheumatic or potentially rheumatic child, simply as a measure of prophylaxis against acute rheumatism. Removal should only be undertaken if there is some definite indication.

4. Observations have been detailed on the relative incidence of nasopharyngeal infections upon the tonsillectomized and the non-tonsillectomized pupils of a school population numbering nearly 14,000. Most of these pupils were between the ages of 13½ and 18, and belonged to the well-to-do classes. Save for two, with a total of 1,100 pupils, all the schools were boarding schools. Rather more than half of this population was tonsillectomized. Some of the observations cover a period of seven terms, or two and one-third years, whilst others are confined to certain terms of epidemic prevalence.

5. These interim observations (so far as they have gone) give no statistical support to the theory that the removal of tonsils closes an entrance for infectious or respiratory diseases. Hardly any cases of diphtheria have occurred, so that the prophylactic value of the operation in this disease could not be assessed. In scarlet fever, otitis media, and mastoid disease no significant differences were observed. In the two latter diseases the slight differences observed were in favour of the non-tonsillectomized.

6. These observations, based on actual *attack rates* in a school population, generally support the conclusions arrived at by Cunningham from a study of the *histories* of a similar number of somewhat older students. She found that the tonsillectomized pupils gave a history of higher incidence of all illnesses, and suggests that the fact that children who are often ill are those most frequently tonsillectomized may be the explanation. Comparing the proportion of the amount of illness reported before and after tonsillectomy in the same pupils, she suggests that the removal of tonsils had little influence in lessening the susceptibility to most infections.

7. We hold no brief for the retention of diseased or really obstructive tonsils or adenoids, nor do we wish to cast doubt upon the high value of the operation in cases in which there is sure evidence of toxic or obstructive damage. A review of the literature and the epidemiological observations made on a highly tonsillectomized child population suggest, however, that the excellent end-results of tonsillectomy in selected cases have been statistically overweighted by indifferent end-results in cases in which the operation has been performed without sufficient indications as a more or less routine prophylactic ritual. In our opinion, a large proportion of the tonsillectomies now done in children are not necessary, entail some risk, and give little or no return.

Error in Cancer Statistics

(Abstracted from the *Medical Press and Circular*,
New Ser., Vol. CXXXIV, August 31st, 1932, p. 157)

THE statistics heretofore published do not prove, according to Dr. K. Wolf, of Budapest, the assumption that the rate of mortality from cancer shows a rising tendency. A relative rise is the obvious corollary of the fact that the number of deaths from other curable and preventable diseases is diminished; but this means only that no defence against cancer exists because of ignorance concerning its cause, therapy, and its prophylaxis.

The average duration of life is steadily increasing everywhere, and cancer is the disease of old persons. If there are more elderly persons, more reach an age at which cancer is apt to occur. In Dr. Wolff's opinion the apparent increase in the incidence of cancer has been too much emphasised, for the mortality-rate of every disease shows oscillations, and the progressive rise in the incidence of cancer may be merely a natural oscillation. According to Dr. Zalka the error in the mortality statistics of gastric cancer is 31 per cent.; in uterine cancer 7 per cent.; in rectal cancer 19 per cent.; and in oesophageal cancer 130 per cent. His statistics, founded upon the necropsies performed upon patients over twenty years of age in the Budapest University Clinic, show a cancer-rate of 12.52 per cent. between 1919 and 1923, and he holds that these are more reliable than the older statistics. They show no progressive increase of cancer.

Radical Cure of Hernia: Regional Anæsthetic

By J. C. O. BRADBURY, M.B.C.S., D.M.C.P.

(From the *Practitioner*, Vol. CXXIX, No. 4, Oct., 1932, p. 510)

As a general practitioner of nearly thirty years' standing, faced with the operation of a radical cure for a right inguinal hernia of sixteen years' duration, I had to consider the choice of a general or local anæsthetic. Being somewhat subject to catarrh, though rather dubious whether I might move and interfere with the operator's work, I decided on the local and was backed up by the surgeon, Mr. Molesworth:—

In the morning I had a light breakfast and a cup of bovril at 10.30 A.M. My operation was fixed for 2 P.M. At 1 o'clock I had a hypodermic injection of omnopon gr. 1/3, scopolamine gr. 1/150, which in twenty minutes made me feel extremely confident of myself, and by the time I was in the operating theatre I felt somewhat drowsy, but knew exactly what was being done, and at the same time was most comfortable. The surgeon now began small intradermal injections of percain 1/1000 with a tiny hypodermic needle, this being a preliminary to the larger doses of the same which were given with a full-sized hypodermic needle and a large syringe. I had a slight pain when the deep muscles of the abdomen were injected, but this was really very slight. There was again some twinge of colic when the peritoneal sac was injected. I think the full time for the injection took from seven to ten minutes. I was now able to lie quite still whilst the whole of the operation was performed. The surgeon told me I should have a little pain while he pulled on the peritoneal sac and tied it off, but this again was very slight. I did not watch the operation, and was surprised when told that the skin incision was going to be closed.

I was away from the ward an hour, and it is true to say I did not have two minutes' pain or discomfort

whilst the operation took place. When I got back to bed I was quite comfortable, and after an hour had a cup of tea, but felt sleepy for three or four hours after, when the effect of the local anæsthetic began to wear off. I had little or no pain in the wound except when I coughed, when there was the usual tension on the stitches.

I may mention that I had the ordinary operation (Bassini's) and that the after-treatment of remaining in bed three weeks was carried out. Possibly this brief account may persuade others who are now enduring the discomfort of an ill-fitting truss to undergo the radical cure for hernia.

Aphorisms

(Abstracted from the *Medical Press and Circular*, New Series, Vol. CXXXIV, No. 4876, 19th October, 1932, p. 311)

WISDOM is the daughter of experience.—*Leonardo da Vinci*.

Nevertheless, I have always thought it a greater happiness to discover a certain remedy for even the slightest disease than to accumulate even the largest fortune, and whoever compasses the former I esteem not only happier, but wiser and better too.—*Sydenham*.

Living to old age 'goes in families'; and so does dying before old age.—*Pagel*.

Never believe what a patient tells you his doctor has said.—*William Jenner*.

The best physician is the most conscious of the limitations of his art.—*Benjamin Jowett*.

Every medical student should remember that his end is not to be a chemist, or a physiologist, or an anatomist, but to learn how to recognise and treat disease, to become a practical physician.—*W. Osler*.

Physical signs in the lungs are signs of physical conditions; their pathological significance is a matter of inference.

The special features of syphilitic eruptions are asymmetry and polymorphism.

All pyrexial states in old people are apt to set up a typhoid condition, because the kidneys are unequal to the task of depurating the blood.

In the typhoid state never use depressing antipyretics, e.g., the coal-tar derivatives.

A normal temperature may be present in diphtheria and pneumonia.

In typhoid fever occurring in children, the temperature may be normal or subnormal in the morning (hence the synonym 'infantile remittent fever').

Oedema of the chest wall in the presence of pleuritic effusion is a diagnostic sign of the effusion being purulent.

A high temperature cannot be relied upon to decide the diagnosis between inflammatory and malignant disease.—*A. T. Brand and J. H. Keith*.

Reviews

THE MEDICINAL AND POISONOUS PLANTS OF SOUTHERN AFRICA.—By Professor J. M. Watt, M.B., Ch.B. (Edin.), and M. G. Breyer-Brandwijk, Ph.D. doct. (Utrecht), Apotheker (Utrecht). Edinburgh: E. & S. Livingstone, 1932. Pp. xx plus 314. Illustrated. Price, Rs. 18-12. Obtainable from Butterworth and Co. (India), Ltd., Calcutta.

THE study of the indigenous drugs of ancient civilizations has attracted scientists for a long time. Many of the potent and efficient therapeutic remedies in the armamentarium of the modern physicians are the fruits of enquiry and investigation into the domain of the indigenous medicine of India, China and Egypt. African civilization was shrouded in darkness and mystery for

a very long time, and for want of authentic information on the medicinal plants of that vast country, scientists could not probe into the rich materia medica and folk-medicine of the Hottentots, Bantus, Bushmen and other native tribes of Africa. In the treatise under review, the authors have collected and systematised a mass of information on the medicinal and poisonous plants of South Africa. There is no doubt that the book will be of very great service to all those who are interested in the indigenous drugs of the country and will pave the way for further research and investigation.

The book will also be interesting to those who are working on the indigenous drug problems in India. Many of the 'natural orders' of South Africa are found

in abundance in India, and the description of the pharmacological and toxicological properties might be of help to workers in this field in India. The get-up of the book is excellent and the illustrations, both coloured and uncoloured, are beyond reproach. The bibliography at the end of each section shows that a good deal of time and energy has been devoted towards this side, though Indian workers would miss many references to important papers published in India. The indices of botanical names, common English and African names and active principles appear to have been carefully prepared and are conveniently arranged. The book should be kept in the libraries of all big educational institutions for purposes of reference.

R. N. C.

INDIGENOUS DRUGS OF INDIA: THEIR MEDICAL AND ECONOMIC ASPECTS.—By LIOUT.-COL. R. N. Chopra, M.A., M.D. (Cantab.), I.M.S., Professor of Pharmacology, Calcutta School of Tropical Medicine. Calcutta: The Art Press, 1933. Pp. 655. Price, Rs. 15.

THE publication of this unassuming, yet very important, book marks what we hope to be a very definite step forward in the progress of Indian medicine. It is the result of twelve years of intensive study of the problems involved and of very hard work by the author and his colleagues, much of which has been published in our columns. As Colonel Chopra has repeatedly pointed out, there are three main problems concerned; (a) the fact that many plants official in the British Pharmacopoeia grow in India, and that from these plants official B. P. preparations could be manufactured at a cost very much less than that now paid for the same articles when imported. *Digitalis* is a good example; the plant has been cultivated at Kumaon, Mungpoo, in Burma and in the Nilgiri Hills, and an official tincture can easily be prepared in India equal to the best imported stock at very much lower cost, and free from the very serious deterioration which this drug undergoes in transit through the Red Sea from Europe to India. (b) Secondly, many drugs equivalent to those official in the B. P. can be manufactured in India from plants indigenous in this country. *Ephedrine* is a good example; five species of this plant grow in northern India and yield an alkaloidal content quite equal to, even if not better than, the Chinese variety which now dominates the market. (c) Thirdly, it is worth while to investigate carefully the properties of those drugs in the indigenous systems of medicine in India which have an established reputation in the treatment of diseases, pharmacologically and clinically, to find out whether they are of therapeutic value or not. The author has been carrying out this work for the past twelve years, and the result is the introduction of such drugs as *kurchi*, and its alkaloid, *conessine*, in the treatment of amoebiasis, and of *kuth* root in asthma. Only by such careful and controlled investigation can the actual value of these drugs be assessed.

All these three factors enter into the making of this book, which one may regard as the precursor to an Indian Pharmacopoeia composed chiefly of indigenous drugs, prepared in India by indigenous drug manufacturers and sold at prices within the reach of the Indian *ryot*. To take another example, there seems to be no good reason to-day why India should export large quantities of tea dust to America, only to buy a good deal of it back as caffeine. Some idea of the expenditure of India on foreign drugs is given on pp. 21 to 24 of the book; thus the import of pharmacopoeial preparations and chemicals reached a figure of 114.3 lakhs in 1927-28, and that of proprietary and patent medicines a figure of 42.8 lakhs. Most of this expenditure is preventable, and its place could be taken by drugs of indigenous origin.

The book is divided into five parts. Part I deals with the medical and economic aspects of Indian indigenous drugs, and here a very interesting historical sketch precedes a general outline of the present position. Part II deals with the potential drug resources of India, taking up separately the pharmacopoeial and allied drugs, one by one. Part III deals with the drugs used in the indigenous systems of medicine, dealing separately with those of vegetable and those of mineral and animal origin. Part IV, 'Indian Materia Medica', must have involved an immense amount of labour in compiling. It commences with a list of references to the literature from 1810 to 1932, followed by one of journals consulted. Then comes a list of Indian medicinal plants, some 3,000 in number, with their vernacular names, their uses in the indigenous systems of medicine, chemical composition, and references to the literature. This list alone is quite unique, and will serve as a standard work of reference for many years. This is followed by lists of inorganic drugs and of those of animal origin used in the indigenous systems, and a miscellaneous section on remedies used in snake bite and scorpion bite, and of plants containing poisonous principles. Part V enumerates the common bazar medicines of India, giving full vernacular names in all languages, and indications for their use. Finally comes a very full and detailed index of common vernacular names, and a final general index.

No one could ask for any work more authoritative, more detailed, and yet more handy on the subject. The Indian medical practitioner and the Indian chemist will find here everything that he requires in the way of information, whilst the research worker will find full guidance to the literature on his subject. The book is not only timely in its appearance, it should meet a very long-felt want, and supplant much of the literature which is now so old and out-of-date. We cordially welcome its appearance and desire to bring it to the special attention of our readers.

A last word must be said in praise of the publishers. Paper, printing, and binding leave nothing to be desired, and in these respects the book is far and away above the standard of the ordinary medical book published in India. Both the author and his publishers are to be warmly congratulated on its publication.

R. K.

'MATERIA MEDICA, PHARMACOLOGY AND THERAPEUTICS.'—By W. A. Bastedo, Ph.G., M.D., Sc.D. (Hon. Columbia), F.A.C.P. Third Edition. Reset. Philadelphia and London: W. B. Saunders Company, 1932. Pp. 739. Illustrated. Price, 32s. 7d.

PROFESSOR BASTEDO'S book was very well received on its first appearance in 1913 and since then it has been a constant source of inspiration to students and teachers alike; this is evidenced from the number of reprints and editions it has passed through. Chemistry, physiology, pharmacology and the allied sciences have made rapid strides during the last two decades, and a large number of new remedies have been introduced into medicine and therapeutics. The recent edition of Professor Bastedo's book has been largely expanded, revised and rewritten wherever necessary, to cover every advance in these fields. The sections dealing with alcohol and *digitalis* have been brought up to date and are extremely interesting. Students will get all the newer knowledge with regard to insulin, ovarian hormones and their application in menstrual disorders, the hormones of the anterior pituitary, *ephedrine*, and drugs such as *plasmochin*, and dyes stuffs. The text on the whole is clear, instructive and accurate, and the book can be strongly recommended by all teachers to their students going up for university examinations.

R. N. C.

MATERIA MEDICA, PHARMACY, PHARMACOLOGY AND THERAPEUTICS.—By W. Hale-White, K.B.E., M.D. (Lond.), M.D. (Dub.), LL.D. (Edin.). Twenty-first Edition. Revised by A. H. Douthwaite, M.D., F.R.C.P. London: J. & A. Churchill, 1932. Pp. x plus 547. Price, 10s. 6d.

DR. HALE-WHITE's book was first published in the year 1892, nearly 40 years ago. Since then, the book has been reprinted several times and has passed through twenty editions. This speaks in no uncertain terms of the great popularity of the book among the students and teachers of medicine. It is not too much to say that wherever western medicine is taught and read, Dr. Hale-White's book is well known. Medical and allied sciences have made rapid progress during recent years and nowhere is the advance more evident than in the sciences of pharmacology, pharmacy and therapeutics. The great merit of Dr. Hale-White's *Materia Medica* is that it has always kept itself abreast of the modern developments and never failed to create a demand for itself with changing times. The reviewer read the book as a student, and as a teacher of the subject the book is still his constant companion.

The twenty-first, the edition under review, has been thoroughly revised and brought up to date by Dr. Douthwaite. The book has assumed a new garb and those who used the book before will miss the handy volume which they could carry in their pockets. The present edition is, however, quite convenient in size and has maintained the prestige of its predecessors to the fullest extent. On account of the publication of the new British Pharmacopœia, drastic changes have been effected in the list of drugs and their dosages; all these changes have been incorporated in the present volume. We have no doubt that this edition will be as popular as the previous editions.

R. N. C.

THE ELEMENTS OF MEDICAL TREATMENT.—By R. Hutchison, M.D., F.R.C.P. Second Edition. Bristol: John Wright and Sons, Ltd., 1932. Pp. 188. Price, 5s.

THE author of the present volume has written several books which have been a great boon to medical students and practitioners, and this work is no exception. In the 'Elements of Medical Treatment' the author has indicated the management of patients, and the dietetic and medicinal treatment of the common diseases met with in daily practice, in a clear, concise and lucid manner. The large demand for and the popularity of this book is evidenced by the fact that in the two years following its first publication it was reprinted twice and that a second edition had to be published a short time after. In preparing the present edition the author has largely rewritten and brought up to date the chapter on the treatment of anæmia and has added chapters on sedatives and physiotherapy. This book should be in the possession of all medical students working in the hospital wards and in the library of all junior practitioners.

R. N. C.

HEART DISEASE: THE PRINCIPLES OF DIAGNOSIS AND TREATMENT.—By C. Bramwell, M.A., M.D., F.R.C.P. London: Edward Arnold & Co., 1932. Pp. vii plus 244. Illustrated. Price, 12s. 6d.

MUCH has been written and said about the diseases of the heart and circulation, and the number of books on the subject is legion. In these days of specialisation, the tendency of most authors is to present a detailed and exhaustive treatise in which the subject is dealt with from all possible angles and where every detail is attended to. Dr. Bramwell has made no attempt to

cover the whole field of cardiology and has only endeavoured to illustrate the important general principles of the subject. To the advanced cardiologists and veteran research workers, therefore, the book may be found wanting in certain respects, but to practitioners who want to approach their cardiac cases intelligently, the book is sure to make a wide appeal. The book is written in simple and lucid language, and the accounts of the different conditions are particularly free from the ambiguous statements that are so commonly met with in books of this nature. The readers are not likely to lose sight of the main issues involved in a mass of detail which is more of theoretical than of practical value.

The modern outlook on heart disease has been admirably brought out, and stress has been laid on the ætiological factors concerned in its causation. The importance of the murmurs and valvular lesions has been rightly relegated to the background. A systolic murmur by itself alone has been stated to be of little or no consequence from the point of view of prognosis. The significance of the electrocardiographic tracings is very briefly mentioned. In view of the importance of this branch one would have expected a longer dissertation on the subject. The author has also not gone deeply into the question of treatment and drug therapy. In spite of these minor shortcomings the book will form a very useful addition to the library of medical practitioners in this country.

R. N. C.

CLINICAL ENDOCRINOLOGY OF THE FEMALE.—By C. Mazer, M.D., F.A.C.S., and L. Goldstein, M.D. Philadelphia and London: W. B. Saunders Company, 1932. Pp. 519. Illustrated. Price, 30s.

THE endocrines have been the subject of a good deal of experimental and clinical research during recent years. Our knowledge regarding the part played by these glands has greatly increased and we are now in a position to utilise our findings in this field in practical therapeutics. Thus, the value of organotherapy in the treatment of menstrual disorders has now been placed on a definite footing, though scepticism still exists. The authors have been interested for many years in the endocrinology of the female sex glands and have presented the subject in an easy conversational style which will not fail to make a wide appeal to gynaecologists, clinicians and teachers. The book is replete with useful information for laboratory workers who will find it profitable to go through the chapter on the hormone tests for pregnancy. The agents employed in the treatment of disorders of menstruation have been set forth in detail. The indications and contraindications for the use of 'œstrin', the ovarian hormone, and 'progestin', the luteal hormone, have been given and the different forms in which these are available in the market for ready application to patients are recorded. Low dosage irradiation of the pituitary gland and ovaries as a therapeutic measure has also been discussed. The book, though of particular interest to the gynaecologist, will also be useful to the general practitioner. It should find a place in all medical libraries.

UROLOGY IN WOMEN.—By E. C. Lewis, M.S. (Lond.), F.R.C.S. (Eng.). London: Baillière, Tindall and Cox, 1932. Pp. 76. Illustrated with 21 plates and 4 figures in the text. Price, 6s.

THIS is a small volume of 76 pages, which the author states 'is not intended to be a complete treatise on urology but rather to emphasize certain points which have a peculiar application in women patients'. At the end of each chapter illustrative cases are given briefly. The chapter on the kidney is very good. The printing is admirable and the illustrations excellent.

S. A. McS.

ESSENTIALS OF SURGERY.—By M. L. Mitra, M.D., F.R.C.S. (Edn.). Volumes I and II. Second Edition. Calcutta: Scientific Publishing Co., 1932. Pp. vii plus 538 in volume I and 555 in volume II. Price, Rs. 12.

WHEN the number of textbooks on surgery is already so large, the only justification for adding to their number is the publication of a work which presents the subject in a novel way or which meets the needs of a special type of student. The second edition of the above volumes, admittedly not original, is specially written for the requirements of Indian medical students and closely follows the lectures of the author. The subject is presented with admirable clearness, emphasis being laid on tropical surgical conditions as well as the commoner surgical affections. While aetiology and pathology are given due share, clinical features and diagnosis receive full recognition, and treatment is eminently clear, practical, and, as is necessary in an elementary handbook for students, somewhat dogmatic.

The author is to be congratulated on producing one of the best of the many synopses that have been written; it will be found of great help to the student in revision and in preparing for examinations. The size is very handy and the get-up excellent. There are a good many printer's errors which it is hoped will receive attention in the next edition.

V. S.

ONE HUNDRED POPULAR FALLACIES.—By C. W. Budden, M.A., M.D., Ch.B. London: John Bale, Sons and Danielsson, Ltd., 1932. Pp. viii plus 162. Price, 3s. 6d.

DR. CHARLES BUDDEN is a refreshingly graphic writer. He succeeds by this means and through gentle ridicule in driving his points home without making more exaggerated statements than is permissible in articles intended for educational propaganda in matters connected with the people's health.

One Hundred Popular Fallacies was originally published as a series of articles in *Maternity and Child Welfare* and like all articles from Dr. Budden's pen appealed to so wide a public that a reprint in book form is justifiable. The fallacies dealt with are chiefly connected with maternity and child welfare, and range from superstitions so lacking in any foundation that it seems incredible they are still widely held in large areas of the country, to opinions which were at least countenanced, if not expressed, by the family doctor only a few years ago. Some of the fallacies judging from advertisements in the medical journals are, even in these days of enlightenment, popular with the medical profession. Such a belief is the one that thumb sucking can be cured by various appliances instead of by re-education and substitution of beneficial activities for this form of self-indulgence.

Dr. Budden's remark 'we have no use for tonsils' requires modifications perhaps, but the articles as a whole are full of wisdom and understanding, and the reprint makes a very readable book.

J. M. O.

AIDS TO BIOLOGY.—By R. G. Neill, M.A. London: Baillière, Tindall and Cox, 1932. Pp. vi plus 257, with 27 figures. Price, 3s. 6d.

THIS handbook of the Students Aid Series is designed to cover the syllabus of the 'Higher School Certificate' examination of Cambridge and other universities. The subject has been presented in a suitable form for students and the book will be particularly helpful at the time when rapid revision of the subject just before the examination is necessary. The chapters dealing with algae and fungi in section I, and the chapter on sex and heredity in section II are worth special mention. The different theories of evolution have been described

in a clear and concise manner. The complex processes of cell division, which are usually baffling to the beginners, have been illustrated and made interesting. The medical students doing biology in the Indian universities would find the book profitable reading.

PRACTICAL ANATOMY.—By Six Teachers. Edited by E. P. Stibbe, F.R.C.S. London: Edward Arnold and Co., 1932. Pp. xii plus 719. Illustrated. Price, 30s.

THIS book is intended to provide a complete course in practical anatomy to the students going up for the 2nd M.B., the conjoint board and the primary fellowship examinations, and has special features which are not commonly met with in many treatises of this nature. The production is the joint effort of six well-known teachers in the field of anatomy and the various sections have been dealt with by specialists in their particular branches and are rich in anatomical detail. A large number of new and original drawings, some of them very instructive, have been added, and the diagrams in the sections dealing with the orbit and the ear are worthy of special note. Although it is a practical guide, it would appear that the instructions for dissection are not so explicit and detailed as in some of the older books. The book can be strongly recommended to teachers and advanced students in this country.

ANATOMY. Part I. (Catechism Series).—By R. Whittaker, F.R.C.S.E., F.R.S.E. Fourth Edition. Revised and enlarged. Edinburgh: E. & S. Livingstone. Pp. 80. Price, 1s. 6d. Postage, 2d.

THIS small book of the Catechism Series deals with the anatomy of the superior extremity. The muscles and fasciae, the vessels and the nerves have been subdivided into those of the (1) shoulder and arm, (2) forearm, and (3) hand. The joints as well as the ossification of the bones of the whole extremity have been considered together. The relations of the important muscles and the main vessels have been well put. The only criticism that we can offer is that the scapular circumflex artery has been so placed that it might be mistaken for one of the branches of the third part of the axillary artery. The time of appearance of the epiphyses and their fusion with diaphyses are to be accepted with caution in view of the recent radiological observations. The book does not pretend to replace textbooks on anatomy, but is admirably suited for revision work and for refreshing the memory of the students before they sit for their examinations.

N. P.

A TEXTBOOK OF ANATOMY AND PHYSIOLOGY.—By J. F. Williams, M.D. Fourth Edition. Philadelphia and London: W. B. Saunders Company, 1932. Pp. 601, with 416 illustrations, 32 of them in colours. Price, 14s.

THE new (fourth) edition of Dr. William's book will be enthusiastically received by students and teachers alike, of nursing, physical education, physiotherapy, and allied branches of practical arts. The interesting feature of the volume is its close linking of the two important and related subjects, without a good groundwork of which the education of no students in these branches is likely to be sound. Besides purely anatomical and physiological matter, elementary facts of embryology and pathology are given without needless discussion of intricate details. At the end of each chapter, practical exercises and questions are appended which are likely to stimulate the reasoning faculties of the students. The teachers will also be greatly benefited by the select references attached. The illustrations, though generally not coloured, are clear and expressive. The book is up to date in every section and the arrangement shows that the author has got great teaching experience.

Annual Reports

LEAGUE OF NATIONS, HEALTH ORGANISATION, EASTERN BUREAU. ANNUAL REPORT FOR 1931

THE Eastern Bureau of the Health Organisation of the League of Nations was established in order to collect and disseminate information of an epidemiological nature in the Far East more quickly than it could be done through Geneva or through the Office Internationale of Paris. The Bureau is located at Singapore. Information regarding outbreaks and incidence of epidemic disease is sent to the Bureau from Far Eastern countries and is quickly collected and sent by telegram and cable to countries and ports all over the Far East and to several ports and countries outside.

The Bureau also compiles an interesting and useful weekly fasciculus of the incidence of epidemic disease in the Far Eastern area. It also publishes an annual report. Dr. Gautier who has acted as Director of the Bureau since its inception has returned to Geneva and his place has been taken by Dr. Park late of the Australian Quarantine Service. The part played by Indian ports in the dissemination of disease in the Far East is well brought out in the report. Calcutta was the port in which cholera infection was contracted in the case of seven vessels out of 19 infected. Calcutta and Shanghai were the two ports from which smallpox infection was exported to the greatest extent.

Of the two vessels found infected with plague one would seem to have been infected at Rangoon. Bombay, Colombo, Rangoon and Bassien remained plague-infected more or less continuously throughout the year. An interesting feature of the report is the evidence of the increased part that the Republic of China is now prepared to play internationally in health matters. Dr. Wu Lien-Teh, already well known for his work on Manchurian plague, is the head of the new National Quarantine Service of China which is dealing particularly with cholera infection and dissemination. A distressing account is given of the floods in China in 1931, relieved by the descriptions of the assistance given by the organisations of various neighbouring and outside countries.

The Bureau has conducted research and liaison work in plague and cholera. The work of Asheshov and Morison on cholera bacteriophage is reviewed and its possible implications pointed out.

The Bureau is destined and fitted to play an increasingly interesting and useful part in the prevention and control of infectious disease in the Far East.

REPORT OF THE EUROPEAN MENTAL HOSPITAL, RANCHI, FOR THE YEAR 1930. BY LIEUT.-COL. O. A. R. BERKELEY-HILL, M.A., D.M., I.M.S. RANCHI: SUPERINTENDENT, GOVERNMENT PRINTING, BIHAR AND ORISSA

THIS annual report is always a most interesting one. The following abstracts from it will serve to summarize it:—

Accommodation.—The accommodation of the hospital during the year under report remained the same as in the previous year, *i.e.*, for 106 males and 100 females or a total of 206 of both sexes.

Summary of notable changes.—There have been very few changes or innovations to record during the past year. I would like to record the acquisition of portraits of the famous men after whom our wards have been named. First we have to thank Dr. Henry Yellowlees, O.B.E., M.D., of the Retreat, York, for a present of a fine portrait of the humane William Tuke, the founder of that institution. Then we have to thank Dr. Lange of the Psychiatric Institute at Munich, for presenting us with a portrait of the late Professor Emil Kraepelin,

to be placed in the ward named after this great German alienist. Then our thanks are due to Dr. Daniel, Medical Superintendent of Hanwell Mental Hospital, for presenting us with a photograph of the portrait of Dr. John Conolly, the first English alienist who tried to abolish the habitual cruelty with which the treatment of the insane was notorious up to the end of the 18th century. The photograph was enlarged very successfully so that patients, staff and visitors to the hospital can now gaze upon the handsome face and figure of that pioneer in English psychotherapy. I have also to thank my friend, Dr. Edward Mapother, Medical Superintendent of Maudsley Hospital, for his kindness in permitting me to have a reproduction made of the portrait of Dr. Henry Maudsley that hangs in the hall of the hospital he founded and endowed in London. Portraits of William Cullen and Giovanni Battista Morgagni have also been obtained and they now decorate a wall in the ward named respectively after the great Scottish and Italian reformers of psychotherapy. So far we have failed to obtain portraits of Philippe Pinel and Juan Gilaberto Joffre. For the hospital not yet to possess a portrait of Pinel, the greatest of all the opponents of cruelty to the insane, is very much to be deplored, for Philippe Pinel was the first to adopt, in face of much opposition, an attitude of kindness and sympathy in dealing with the mentally disordered. Further, and this is a point that should never be forgotten in the Ranchi European Mental Hospital, the first patient in the Salpêtrière hospital in Paris, whom he selected for more humane treatment, was an Englishman, a sea captain, who had lived in fetters for no less than forty years. It is pleasant to think that this fierce and powerful madman repaid the wisdom and sympathy of Pinel by henceforth constituting himself the protector of the lion-hearted little doctor from any possible risk of assault that he might have run through suddenly liberating patients from the chains which, combined with many other forms of cruelty, had rendered them both violent and dangerous to the staff of the hospital whom they naturally regarded as their persecutors.

The maximum number of patients resident in the hospital on any one night was 213 (106 males and 107 females) against 206 (106 males and 100 females) in the preceding year.

The number of patients resident in the hospital at the beginning of the year under report was 101 males and 103 females or a total of 204 of both sexes as compared with 193 in the previous year.

The admissions (including re-admissions) during the year under report were 78 (37 males and 41 females) as compared with 62 (35 males and 27 females) in the previous year.

The total population of the hospital for the year under review was 282 (138 males and 144 females) against 255 (125 males and 130 females) in the previous year.

The daily average number resident in the hospital during the year under report was 200.61 (99.90 males and 100.71 females) against 199.51 (97.45 males and 102.06 females) in the preceding year.

Percentage of cases 'cured' and 'improved' to daily average strength.—The annexed table shows the ratio per cent. of cases 'cured' and 'improved' to daily average number resident in the hospital during the year under review as compared with the preceding year:—

Cases		1930	1929
Daily average number resident in the hospital	200.61	199.51
Ratio per cent. of cases—			
(a) Cured	9.91	5.95
(b) Improved	22.43	8.57
TOTAL		32.34	14.52

It is satisfactory to note that the number of patients discharged as 'cured', shown in the above table, is considerably higher than that recorded in the previous

year. It is of further interest to note that such patients are all new admissions. Also, it will be noted that the number of cases shown as 'improved' during the year under report is considerably higher than in the previous year. The reasons assigned to this satisfactory state of affairs are mainly two—first, improvements in every direction in therapy which have followed upon the increase in experience among the medical and European nursing staff, and secondly, the necessity that has arisen to keep the waiting list of applicants for admission as small as possible in view of the great importance of early treatment in all forms of mental disorder.

Percentage of cases 'cured' and 'improved' to direct admissions.—The table appended below gives comparative data relating to percentages of cases 'cured' and 'improved' to direct admissions during the last two years:—

	1930	1929
Total population	282	255
Compare—		
Direct admissions	78	62
(a) Ratio per cent. of cases 'cured' to direct admissions	20.51	12.90
(b) Ratio per cent. of cases 'improved' to direct admissions	21.79	20.97

Distribution of period of hospital life of patients discharged cured.—The distribution of periods of hospital life of those who left 'cured' during the year under report and in the previous year is shown in the annexed table:—

Period	CASES		
	1929	1930	Total
Under two months	5	6	11
Over two months and under four months	3	10	13
Over four months and under six months	2	2	4
Over six months and under eight months	1	1	2
Over eight months and under one year	1	..	1
Over one year	1	1
TOTAL	12	20	32

The figures in the above table indicate that if patients in the early stages of mental disorder are properly treated in a mental hospital, they have a good prospect of early recovery.

Death-rate.—The death-rate calculated on the average number daily resident in the hospital during the year under report was 6.92 which compares favourably with 7.05 in the preceding year.

Among the patients who died, there was one male who died of rupture of the spleen as a result of injury inflicted by another patient, and one female who suddenly died of suffocation in the ward during an epileptic fit.

Bodily ailments.—The daily average number of cases treated in the hospital for bodily ailments was 5.45 as compared with 0.39 in the previous year, giving an increase of 5.09. The large increase in the proportion of admissions into the hospital was due largely to the increase in the incidence of malaria and influenza, the former being responsible for 37 cases and the latter for 42 cases, and partly to repeated re-admissions.

Malaria still plays an important rôle in the causation of most of the sickness. It has been repeatedly brought under notice in the previous reports of this hospital that the incidence of this disease is progressively high. The same remark is still applicable. Every practicable step has been taken by us from time to time to combat the growing menace of malaria-carrying mosquitoes, but owing to the vastness of the breeding grounds scattered all over the area of Kanke, we have met with little success. Although it is impossible totally to eradicate

this pest, it is within the range of possibility to deal effectively with the mosquito problem, if concerted action were taken by the two mental hospitals (European and Indian), the Agricultural Farm and other Departments stationed at Kanke. Nothing short of this will be of any avail. Accordingly, I addressed the Director of Public Health of this Province in December 1929 on this subject, as a result of which his Assistant in charge of the Chota Nagpur Circle has carried out an investigation as to the extent of mosquito breeding in the area of the European and the Indian Mental Hospitals, the Agricultural Farm, and other places at Kanke, and compiled a report embodying the results of his investigations and indicated therein on what lines a campaign against the mosquito nuisance should be carried out. He suggested, among other things, that the paddy cultivation in the Kanke area might have to be stopped, as the paddy fields are favourite breeding places of malaria-carrying mosquitoes, and emphasised the necessity of appointing a common supervisor or sanitary inspector in charge of the special programme of work suggested by him. The matter is now under consideration of Government.

Health of patients (Physical).—In spite of the striking incidence of sickness, the general health of patients has been good throughout the year under report, and apart from the outbreak of influenza which did not develop to the intensity of an epidemic, there has been no other illness of an epidemic character.

Parole.—It has been more and more realized how valuable the policy of giving parole to patients is an aid to their recovery. As far as possible, all patients of this hospital who are not dangerous to themselves or others, were allowed local and Ranchi paroles. This was also granted to a large number of chronic and incurable cases some of whom were demented considerably, and it was found that they derived a great benefit as a result of receiving this privilege. I am glad to record that in spite of the greater latitude of freedom allowed to them there were no untoward occurrences.

Forms of mental disorder in patients treated.—The following table shows the principal types of mental disorder treated in the hospital during the year under report and in the previous year:—

Types of mental disorder	1929	1930
Circular insanity	21	21
Confusional insanity	3	7
Delusional insanity	17	19
Dementia præcox	54	55
Imbecility	25	29
Insanity from other causes	39	28
Mania	8	13
Melancholia	5	7
Secondary or terminal dementia	53	62
Senile dementia	5	3

Dental treatment.—In view of the increasing recognition of the general harmful effects of oral sepsis, its treatment is an indispensable measure in procuring restoration of the general health and corresponding improvement in mental condition of patients. In furtherance of this view, much greater attention has been paid to the condition of the teeth of every newly admitted patient as well as of those who are already resident in the hospital. The Visiting Dentist, Dr. M. M. Das, has attended regularly throughout the year. I take this opportunity of expressing again my appreciation of the skill and tact with which he has carried out his duties, sometimes in difficult conditions.

Treatment of mental conditions.—The problem of the treatment of patients has received throughout the year our careful consideration in the light of added experience and we continue to make as much progress as possible in this direction.

The following important modes of treatment call for notice:—

(i) *Occupational therapy.*—There is a growing recognition that suitable employment is a direct curative agent in that it produces contentment, diminishes

Annual Reports

LEAGUE OF NATIONS, HEALTH ORGANISATION, EASTERN BUREAU. ANNUAL REPORT FOR 1931

THE Eastern Bureau of the Health Organisation of the League of Nations was established in order to collect and disseminate information of an epidemiological nature in the Far East more quickly than it could be done through Geneva or through the Office Internationale of Paris. The Bureau is located at Singapore. Information regarding outbreaks and incidence of epidemic disease is sent to the Bureau from Far Eastern countries and is quickly collected and sent by telegram and cable to countries and ports all over the Far East and to several ports and countries outside.

The Bureau also compiles an interesting and useful weekly fasciculus of the incidence of epidemic disease in the Far Eastern area. It also publishes an annual report. Dr. Gautier who has acted as Director of the Bureau since its inception has returned to Geneva and his place has been taken by Dr. Park late of the Australian Quarantine Service. The part played by Indian ports in the dissemination of disease in the Far East is well brought out in the report. Calcutta was the port in which cholera infection was contracted in the case of seven vessels out of 19 infected. Calcutta and Shanghai were the two ports from which smallpox infection was exported to the greatest extent.

Of the two vessels found infected with plague one would seem to have been infected at Rangoon. Bombay, Colombo, Rangoon and Bassin remained plague-infected more or less continuously throughout the year. An interesting feature of the report is the evidence of the increased part that the Republic of China is now prepared to play internationally in health matters. Dr. Wu Lien-Teh, already well known for his work on Manchurian plague, is the head of the new National Quarantine Service of China which is dealing particularly with cholera infection and dissemination. A distressing account is given of the floods in China in 1931, relieved by the descriptions of the assistance given by the organisations of various neighbouring and outside countries.

The Bureau has conducted research and liaison work in plague and cholera. The work of Asheshov and Morison on cholera bacteriophage is reviewed and its possible implications pointed out.

The Bureau is destined and fitted to play an increasingly interesting and useful part in the prevention and control of infectious disease in the Far East.

REPORT OF THE EUROPEAN MENTAL HOSPITAL, RANCHI, FOR THE YEAR 1930. BY LIEUT.-COL. O. A. R. BERKELEY-HILL, M.A., D.M., I.M.S. RANCHI: SUPERINTENDENT, GOVERNMENT PRINTING, BIHAR AND ORISSA

THIS annual report is always a most interesting one. The following abstracts from it will serve to summarize it:—

Accommodation.—The accommodation of the hospital during the year under report remained the same as in the previous year, i.e., for 106 males and 100 females or a total of 206 of both sexes.

Summary of notable changes.—There have been very few changes or innovations to record during the past year. I would like to record the acquisition of portraits of the famous men after whom our wards have been named. First we have to thank Dr. Henry Yellowlees, O.B.E., M.D., of the Retreat, York, for a present of a fine portrait of the humane William Tuke, the founder of that institution. Then we have to thank Dr. Lange of the Psychiatric Institute at Munich, for presenting us with a portrait of the late Professor Emil Krapelin,

to be placed in the ward named after this great German alienist. Then our thanks are due to Dr. Daniel, Medical Superintendent of Hanwell Mental Hospital, for presenting us with a photograph of the portrait of Dr. John Conolly, the first English alienist who tried to abolish the habitual cruelty with which the treatment of the insane was notorious up to the end of the 18th century. The photograph was enlarged very successfully so that patients, staff and visitors to the hospital can now gaze upon the handsome face and figure of that pioneer in English psychotherapy. I have also to thank my friend, Dr. Edward Mapother, Medical Superintendent of Maudsley Hospital, for his kindness in permitting me to have a reproduction made of the portrait of Dr. Henry Maudsley that hangs in the hall of the hospital he founded and endowed in London. Portraits of William Cullen and Giovanni Battista Morgagni have also been obtained and they now decorate a wall in the ward named respectively after the great Scottish and Italian reformers of psychotherapy. So far we have failed to obtain portraits of Philippe Pinel and Juan Gilaberto Joffre. For the hospital not yet to possess a portrait of Pinel, the greatest of all the opponents of cruelty to the insane, is very much to be deplored, for Philippe Pinel was the first to adopt, in face of much opposition, an attitude of kindness and sympathy in dealing with the mentally disordered. Further, and this is a point that should never be forgotten in the Rar. Mental Hospital, the first patient in the hospital in Paris, whom he selected for more humane treatment, was an Englishman, a sea captain, who had lived in fetters for no less than forty years. It is pleasant to think that this fierce and powerful madman repaid the wisdom and sympathy of Pinel by henceforth constituting himself the protector of the lion-hearted little doctor from any possible risk of assault that he might have run through suddenly liberating patients from the chains which, combined with many other forms of cruelty, had rendered them both violent and dangerous to the staff of the hospital whom they naturally regarded as their persecutors.

The maximum number of patients resident in the hospital on any one night was 213 (106 males and 107 females) against 206 (106 males and 100 females) in the preceding year.

The number of patients resident in the hospital at the beginning of the year under report was 101 males and 103 females or a total of 204 of both sexes as compared with 193 in the previous year.

The admissions (including re-admissions) during the year under report were 78 (37 males and 41 females) as compared with 62 (35 males and 27 females) in the previous year.

The total population of the hospital for the year under review was 282 (138 males and 144 females) against 255 (125 males and 130 females) in the previous year.

The daily average number resident in the hospital during the year under report was 200.61 (99.90 males and 100.71 females) against 199.51 (97.45 males and 102.06 females) in the preceding year.

Percentage of cases 'cured' and 'improved' to daily average strength.—The annexed table shows the ratio per cent. of cases 'cured' and 'improved' to daily average number resident in the hospital during the year under review as compared with the preceding year:—

Cases		1930	1929
Daily average number resident in the hospital	..	200.61	199.51
Ratio per cent. of cases—			
(a) Cured	..	9.91	5.95
(b) Improved	..	22.43	8.57
TOTAL	..	32.34	14.52

It is satisfactory to note that the number of patients discharged as 'cured', shown in the above table, is considerably higher than that recorded in the previous

the former, a good deal of the defect was possibly attributable to the isolation of Kanke, want of reasonable amenities for recreation and the formation of social cliques. The standard of nursing suffered primarily from the novelty of the work and from the utter ignorance of mental diseases and their treatment on the part of the nurses who elected to work here, a defect due to their training in which no attention is paid to the nursing of mental patients. Now with the increase in understanding of the aetiology of mental disorders as well as of the methods of treating them, the standard of nursing is as high as any one could expect in a country like India.

The more I see of the Anglo-Indian women in the capacity of hospital nurses, the more impressed I am by their talent for this eminently womanly profession.

ANNUAL REPORT OF THE MEDICAL OFFICER OF HEALTH, DELHI, FOR THE YEAR 1931. BY K. S. SETHNA, B.Sc., B.Hy., D.P.H. (LOND.), D.T.M. & H. (CAMB.)

DR. SETHNA'S annual reports are characterised by a refreshing candour and straightforwardness. Conditions are described without any attempt to conceal unpleasant facts; nor is the reader in any doubt as to the opinion of the Health Officer in respect of causation or remedy.

The first outstanding fact in the report is the extraordinary increase in the population of Delhi city in the last decade. Since 1921, the population of Delhi city has increased from 246,987 to 347,592, an increase of over 40 per cent. The reasons given are the centralization of the Government of India in New Delhi and the development of railway work. The increase is therefore probably due in large measure to immigration and is not of a permanently increasing nature. The immediate effect however is likely to be embarrassing to the health of the city. Old Delhi is hemmed in on all sides except the west, and expansion in this direction has been unaccompanied by the ordinary municipal amenities; e.g., the supply of filtered water has not yet been extended to this area. The problem of overcrowding is therefore immediate and pressing, and a committee representative of the municipality has given certain recommendations for expansion of the city which ought to receive very careful consideration by Government. The main avenues for expansion are on and over certain government-owned land, of which the greater part is no longer required for Government purposes, now that the centre of gravity of official Delhi has shifted from the Notified Area to New Delhi. Though one may not necessarily predict a similar expansion of population in the coming decade as in the past, still the problem is immediate, and though the dire effects of the overcrowding do not appear to have been reflected in the 1931 returns to the extent that might have been expected, the problem is a very urgent one and demands the most careful and urgent attention by all concerned. Conditions of overcrowding are most likely to be productive of heavy incidence and mortality from phthisis and this is borne out by the returns for this disease. In 1931, on verification, 1,194 deaths are reported from phthisis giving a death rate of over 3 per 1,000—a very high figure touched only by some other northern Indian towns. The problem of housing in tropical cities is everywhere urgent and difficult.

The birth and death rate for 1931 were 43.4 and 27 respectively—both substantial reductions over 1930 (due almost wholly however to the calculations being made on the new 1931 census). The infantile mortality was 201.2 compared with 198.7 in 1930 and 258.6 in 1929.

The continued absence of plague from Delhi is no doubt due in some measure to the vigorous rat killing campaign continued yearly. In 1931, over 250,000 rats were killed. *X. astia* is the predominant rat flea.

Typhoid fever accounted for 412 deaths—a very high figure. The causes are no doubt the elementary form of conservancy, flies, carriers, and an insufficient and

at times unsatisfactory water supply. Dr. Sethna would hold that the last named is the most potent cause, due to contamination of old and leaky pipes from gross sub-soil pollution. Though supported by medical opinion, this conclusion seems to be disputed by certain lay members of the Committee, and little seems to have been done in the way of remedy. We were under the impression that with the installation of a water carriage system for New Delhi, advantage would be taken to combine old Delhi in the scheme. This seems not to have been the case and the dumping of nightsoil on the outskirts of the city seems to continue with all its attendant dangers and the nuisance of fly breeding still goes on, though the health authorities do their very best.

As regards malaria only 12 deaths were reported but verification by the health staff showed that no fewer than 442 deaths were attributable to malaria. The problem of malaria in and around Delhi has been investigated and reported on at various times. The usual routine measures have been taken but municipal powers seem insufficient to deal with wells.

Maternity and child welfare work is on a good footing; 9 centres exist in the town with a model centre at Bara Hindu Rao attached to the Lady Reading Health School.

The problems of Delhi are thus seen to be mainly of the elementary environmental nature, viz, excretal disposal, water supply and housing. There is no excuse in a modern Indian city for continued neglect of the first two, though housing is a much more difficult matter. Dr. Sethna's report indicates clearly the problems and ways of advance, and we trust that future annual reports will be able to report substantial progress. Dr. Sethna and his staff are to be congratulated on an excellent record of work and energy and on a clearly presented report.

Correspondence

'MILK INJECTIONS IN SPLENIC ENLARGEMENTS DUE TO MALARIA'

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—The conclusions drawn by the author of the above article in the September 1932 issue of your journal seemed to be so very attractive, that it was decided to give this method an immediate trial in our hospital. Accordingly two groups of patients were selected, one of recent cases and the other one of chronic with typical 'ague-cake' spleens. In the recent cases the action of the injections in reducing the size of the spleens seemed to be very doubtful inasmuch as this action is obtained even by the ordinary routine line of treatment of administration of quinine and rubbing of red ointment over the splenic area which of course was kept up in these patients in addition to the milk injections. But in the old and chronic cases the milk injections have absolutely no effect whatsoever and the very bright picture drawn by the author of the article seemed to be very disappointing in our cases.

In short, acute cases of enlarged spleens due to malaria respond quite well to the daily routine treatment of quinine and red ointment. Chronic cases of enlarged spleens due to malaria, in whom milk injections were given according to the author's method and suggestion had not the slightest effect in reducing the spleens, though I venture to say, these spleens eventually become small under the prolonged usual treatment. It is quite possible that the author coming new to a new district came across all acute cases of malarial fever with enlarged spleens, and on giving the milk injections must have been charmed with the result; but those spleens would have disappeared under the usual treatment.

as 1:500 can be employed without damage to the tissues. In non-suppurating wounds the wound may be cleansed with the 1:1,000 solution, the cavity then packed with gauze soaked in the same solution; in suppurating wounds free drainage must first be established, the wound swabbed out once or twice daily with swabs soaked in the same solution, and packed with gauze soaked in it.

In gonorrhœa as a lavage a 1:1,000 to 1:5,000 solution is employed and should be made up in normal saline, being injected twice daily; oral treatment with $\frac{1}{2}$ gr. tablets is also recommended. In local septic conditions the drug may be used as a local application in 0.1 to 1 per cent. aqueous or alcoholic solution. As a poultice 0.6 gm. of 'Acriflavine, B. D.' should be mixed with 4 tablespoonfuls of rice starch, one pint of boiling water added, and the whole boiled until the mixture thickens. Intravenous injection of a freshly prepared 0.5 per cent. solution in a dosage of 1 c.cm. per 10 lbs. of body weight has been reported on favourably in Malta fever, typhoid, meningococcal septicæmia, and also in uterine infections. In pulmonary tuberculosis the hypodermic use of 5 minims doses of a 1:1,000 solution—3 doses in 48 hours—has been recommended. In midwifery a 1:500 solution in glycerine is a valuable and non-irritant lotion, whilst in dentistry 1 to 5 per cent. solutions may be employed for use as a mouth wash in the treatment of pyorrhœa, putrid root cavities, and other cases of oral sepsis.

The drug is put up in powder form, in pessaries, in 1:100 and 1:1,000 solution, and in tablets. The brochure mentioned will be of interest to medical men in general.

LONDON MEDICAL EXHIBITION, NEW HALL, ROYAL HORTICULTURAL SOCIETY, WEST- MINSTER, 17TH TO 21ST OCTOBER, 1932

Notes on the Burroughs Wellcome and Co. Exhibit

The distinctive exhibit of Burroughs Wellcome and Co. demonstrated the attainments in purity and therapeutic efficiency of their products.

Acidosis.—Medical men could test for themselves the palatability of 'Tabloid' Alkaline Compound, Effervescent, a water-dispenser to provide a continuous supply of water having been installed. On solution in water this product provides an effervescent antacid draught, useful as an alkaline diuretic or as a systemic alkaliniser to restore the acid-base equilibrium in acidosis.

Cardiac conditions.—For digitalisation in cardiac conditions 'Diginutin'—a stable solution of the total glucosides of digitalis leaf—may be administered with confidence that the therapeutic effect of digitalis will be attained. For use by ambulatory patients 'Tabloid' 'Diginutin' will be found convenient.

Obstetrics and gynaecology.—'Ernutin' is a clear solution which contains ergotoxine, in definite amount and in a state of chemical purity. 'Ernutin' (oral) contains 0.033 per cent. ergotoxine ethanesulphonate. 'Hypoloid' 'Ernutin' for use by injection contains 0.1 per cent. of ergotoxine ethanesulphonate. Ergotoxine Ethanesulphonate originated and introduced by Burroughs Wellcome and Co. in 1925 is now official. 'Tabloid' Hypodermic Ergotoxine Ethanesulphonate is available.

Radiography.—For use in the radiographic examination of the gall-bladder 'Stipolac' Tetraiodophenolphthalein is supplied in two tubes containing 'Stipolac' Sodium Tetraiodophenolphthalein (Iodophthalein, B. P.) and 'Stipolac' Acid Mixture.

Serological products.—A representative selection of 'Wellcome' Serological products prepared by The Wellcome Physiological Research Laboratories, Beckenham, Kent, England, and distributed by Burroughs Wellcome and Co., formed a section of the exhibit. 'Wellcome' concentrated Gas-Gangrene Antitoxin (*Perfringens*)—Globulins (*B. welchii* = *B. perfringens*) is used for the treatment and prophylaxis of the toxæmia of acute

intestinal obstruction; in certain cases of puerperal septicæmia following abortion; and as a prophylactic against gas-gangrene in grossly infected wounds such as occur in road accidents.

Vitamines.—'Kepler' Cod-liver Oil with malt extract presents vitamins A, B and D in their natural association and is a valuable extra-dietetic agent, especially in childhood and convalescence. A supplementary source of vitamin D is 'Tabloid' Irradiated Ergosterol, while 'Tabloid' Carotene exhibits the characteristic properties of vitamin A.

Medicine chests and cases.—A display of 'tabloid' medicine chests and cases was flanked by photographs of 'tabloid' medical equipment supplied to historic expeditions. A medicine chest carried by Sir H. M. Stanley in the Emin Pasha Relief Expedition in 1887 and rediscovered recently in the Government Medical Stores, Nairobi, Kenya, has been presented to the firm by the Government of Kenya.

The photoscopes.—By means of the photoscopes the characteristic appearance in bold relief of a number of pathological conditions could be viewed. These included leprosy, yaws, syphilis, oriental sore, kala-azar, goitre, cretinism, scurvy, lupus, rickets and acromegaly. Numerous charts and diagrams indicated the trend and attainments of medical science.

MELLIN'S FOOD

The proprietors of this well-known food are issuing a very attractive calendar.

This may be obtained by application to Messrs. Mackenzie Lyall and Co., 5, Mission Row, Calcutta.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which may be added to the subscription. The envelopes are strongly made and the *Gazette* does not need to be folded.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

A CASE OF 'ABNORMAL BLOOD GROUP' IN WHICH TRANSFUSION WAS PERFORMED

By R. B. LLOYD, M.A., M.B., B.Chir. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

Imperial Serologist

and

S. N. CHANDRA, M.B.

Assistant Serologist

(Results expressed in the international nomenclature)

MRS. F. J., an Armenian aged 25, was admitted to the Presidency General Hospital, Calcutta, suffering from anæmia and mammary abscess subsequent to childbirth. The breast was opened and drained, about half a pint of pus being evacuated. Except for an attack of kala-azar six years ago her medical history is unimportant. Her obstetric history is that her first and second children died at the age of one month from 'pneumonia', the third child is alive and apparently healthy, and her fourth pregnancy terminated in the birth of a dead child, three weeks before the present admission to hospital. She has never had a blood transfusion.

On admission she was intensely anæmic and up to the present date has suffered from fever of the continued type. The Widal reaction was negative. The Wassermann reaction was positive, which is interesting in view of the obstetric history. There was some enlargement of the liver and slight enlargement of the spleen. The formalin reaction of the serum for kala-azar was doubtfully positive. It is not possible to determine whether these latter findings are due to the previous attack of kala-azar or to the present attack of syphilis or to both causes. There was no enlargement of lymphatic glands. Blood examination showed the following:—

Red cell count	640,000 per c.mm.
White cell count	5,000
Hæmoglobin	10 per cent.

Differential white cell count:—

Polymorphonuclears	64 per cent.
Lymphocytes	32
Eosinophils	2
Basophils	1
Large mononuclears	1

No abnormal cells were seen.

It will be observed that the anæmia is profound, and that there is no evidence of a polymorphonuclear leucocytosis in response to the septic infection terminating in the large abscess from which *Staphylococcus aureus* was isolated.

As it was desired to perform a blood transfusion, specimens of citrated cells and of whole blood were sent to us as usual for blood grouping tests and the selection of a suitable donor.

Her cells tested for iso-agglutination against sera of known groups yielded the following reactions:—

With group O serum	+
With group A serum	+
With group B serum	+

Therefore as judged from her cells her blood group is AB. Her serum tested for iso-agglutination against cells of known groups yielded the following reactions:—

With group O cells	—
With group A cells	+
With group B cells	—

These serum reactions are abnormal in a blood whose cells are of group AB. Since abnormal types are classified according to the agglutinogens present, the provisional conclusion is that this blood is of group AB with an additional abnormal factor present in the shape of an anti-A agglutinin. As we shall see later, evidence was obtained of the presence of an anti-B agglutinin also.

The following experiments were carried out to determine the nature of the abnormality. For these tests the cells of the patient and those of all persons used for control tests were washed three times, each washing occupying 15 minutes. Using washed cells the above grouping tests were repeated with results identical with those shown above, which were obtained with unwashed cells.

Tests of the patient's cells

1. The cells of the patient were again tested against a fully controlled group O serum. The agglutination was positive. The group of the patient being assumed to be AB, this experiment must yield a positive result.

2. The cells of the patient were tested against six sera of group A, yielding a positive agglutination in each case. This is also the correct result for cells of group AB.

3. Similarly, the cells of the patient were tested against six sera of group B, yielding positive agglutination in each case. This is also normal for cells from a blood of group AB.

Tests of the patient's serum

1. The patient's serum was now tested against cells taken from two fully controlled bloods of group AB. In both cases a positive agglutination was obtained. In one case the reaction was strong, while in the other it was weak. This result is highly abnormal, since the patient's serum agglutinated cells of her own group. The abnormality clearly lies in the patient's serum.

2. The patient's serum was also tested against six sets of group A cells, all fully controlled, yielding a positive agglutination in every instance. This result is also abnormal, since the anti-A agglutinin should not be present in serum from a blood of group AB.

3. The patient's serum was also tested against five sets of group B cells, all fully controlled. This experiment yielded two positive agglutinations, two negative and one positive (weak). This result, which is also abnormal, shows that anti-B agglutinin is also present, though apparently in low titre, since out of five tests two were negative and one positive (weak), and in the original grouping experiment at the head of this paper no evidence of the presence of anti-B agglutinin was obtained. It is well known that the titre of the anti-B agglutinin is often lower than that of the anti-A agglutinin, and the weak positive result obtained in one of the tests detailed in experiment No. 1 above on the patient's serum is probably partly attributable to the low titre of the anti-B agglutinin.

4. The patient's serum was tested for agglutination against her own washed cells. The result was negative. There is thus at laboratory temperature no evidence of auto-agglutination.

5. The patient's serum was tested for agglutination against her own washed cells in the refrigerator. The result was strongly positive, showing that auto-agglutination is present. On placing the preparation in an incubator at 37°C, the agglutination had completely disappeared in five minutes. The reaction is thus reversible.

Absorption tests

The following absorption tests were carried out:—

1. The patient's serum was absorbed overnight in the incubator at 37°C with group A cells. The absorbed serum was then tested for agglutinating power and gave the following results:—

With group AB cells +
With group A cells —
With group B cells +

The absorption has thus removed the anti-A agglutinin.

2. Similarly, the patient's serum was absorbed with cells from one of the group B bloods which yielded a positive agglutination in test No. 3 above with the patient's serum. After absorption, this serum was tested for agglutinating power and gave the following results:—

With group AB cells +
With group A cells +
With group B cells —

This experiment shows that the anti-B agglutinin has been removed by the absorption. It follows that both the anti-A and anti-B agglutinins were present in the unabsorbed serum.

3. A group O serum of known normal reactions was now absorbed with the patient's cells, and the absorbed serum was tested against two sets of group A cells and two sets of

group B cells. In all four tests the agglutination was negative. Since group O serum contains both the anti-A and the anti-B agglutinins which are completely removed by this absorption, this experiment demonstrates the existence of 'A' and 'B' agglutinogens in the patient's cells, thus confirming the correctness of the earlier assumption that the 'normal' group of the patient is AB.

This patient's blood thus contains both 'A' and 'B' agglutinogens and a and b agglutinins, a combination which, if effective *in vivo* at body temperature, would be incompatible with life.

Tests to investigate the connexion, if any, between the abnormal blood group and the auto-agglutination

Fortunately sufficient material was available to permit of these crucial tests being carried out in a test tube, and it will be seen later how this circumstance enabled us to determine the nature of the abnormality.

The patient's washed cells were placed with her own serum in the refrigerator overnight (using an excess of cells). As before, a strongly positive agglutination was obtained. After the absorption, the supernatant serum was withdrawn by capillary pipette while the whole preparation was still in the refrigerator. This absorbed serum was now tested against cells of groups A and B yielding negative reactions in both cases.

This experiment demonstrates that after removal of the auto-agglutinins by cold fixation the serum has reverted to normal as regards iso-agglutinins, since in group AB the serum has no agglutinating power. Sufficient material was available to permit of the repetition of this test on a subsequent day, and the results were identical.

We have thus been able by absorption in the cold to dissect, as it were, the agglutination phenomena produced by this serum of 'abnormal group' into two components which separately produce:—

(i) Entirely normal reactions corresponding to group AB (absence of iso-agglutinins).

(ii) Auto-agglutination, which, in so far as the patient's own cells are concerned, exhibits the usual properties of occurring only in the cold and being reversible on warming, yet occurs at laboratory temperature with cells of groups A and B and even with cells of other group AB persons, *i.e.*, the same group as the patient.

We again performed this experiment of placing the patient's cells and her serum in the refrigerator overnight, but instead of pipetting off the serum in the cold, we varied the technique by removing the preparation from the refrigerator and centrifuging it at laboratory temperature and then pipetting off the serum for test. The time occupied by this operation was two minutes. The absorbed serum obtained under

these conditions yielded the following reactions:—

With group A cells +
With group B cells ±

It will be seen that by this variation in technique an entirely different result is obtained. This last experiment demonstrates the surprising rapidity with which the auto-agglutinins again become free in the serum when the preparation is even slightly warmed, reproducing the apparent 'group abnormality'.

We are thus dealing with a blood whose cells give normal reactions for group AB, and whose serum also gives normal agglutination reactions—these are of course *nil* in the case of group AB—provided the auto-agglutinins present are rigidly excluded by decantation of the serum under strict refrigerator conditions after absorption with the patient's own cells.

We now desire to refer to a previous publication by us on a very similar case (Lloyd and Chandra, 1930). Both the patients were women, both were suffering from anaemia, in both the basic group was AB, and in both cases auto-agglutinins were demonstrated. In our former case the cold-box absorption tests to remove the auto-agglutinins could only, owing to shortage of material, be carried out once on a slide. In view of the reactions of the present case which demonstrate the amazing rapidity with which auto-agglutinins fixed by the patient's own cells in the cold again become free on the slightest warming, we have to admit the possibility that the technique described in our former paper for removal of the auto-agglutinin may not have been entirely adequate. This involves the possibility that the post-absorption agglutinations in our first case were in reality due to released auto-agglutinin, and not, as we thought at the time, to an independent abnormality. If this be so, the two cases fall into the same class, both exhibiting auto-agglutination at laboratory temperatures against cells of groups A and B, and even in the latter case against cells of group AB, though against the patient's own cells the agglutination only occurs in the cold, being reversible on warming.

It is of importance to determine whether auto-agglutinins are more prone to appear in the group which has no iso-agglutinins than in any other, or whether it is only a coincidence that in our seven years experience of blood grouping, during which over a thousand such tests have been carried out, only two instances of auto-agglutination have been found, which in both cases were in group AB blood.

It is natural to suppose that, when this patient was in a condition of health, she had a normal group of the AB type, and that, connected in some way with the onset of the grave anaemia, the auto-agglutination effect developed. This being added on, as it were, to the normal reactions of the blood suggests the existence of an abnormal blood group. If this patient

survives, as seems possible, we hope to be able to examine her blood again some months hence in order to see the effect of recovery on the auto-agglutinins.

As regards the possibility of blood transfusion, we first reported to the physician that in view of the abnormal reactions of the patient's blood we could not guarantee any donor as safe, and recommended that blood transfusion be not given. The physician, however, considered that without a blood transfusion the prognosis was so grave that the risk of untoward results from a transfusion must be faced. We were asked to reconsider the question from this point of view, and we agreed, on the understanding that the laboratory incurred no responsibility, to provide a donor. Even though the patient's serum does not agglutinate her own group AB cells *in vivo*, we must, in selecting a donor, depend upon the reactions of the blood examined *in vitro*. As her serum agglutinated group AB cells *in vitro*, transfusion with group AB blood was clearly inadmissible. She was therefore in the curious position of being debarred from receiving blood of her own group. As both anti-A and anti-B agglutinins were present in the serum it was clear that the only chance for this patient was a donor entirely devoid of agglutinogens, *i.e.*, one of group O. In view of the possibility of further abnormal reactions, we carefully tested the serum of the patient against the cells of the selected group O donor, the result being negative as it should be. We accordingly advised the physician that theoretically there was no more risk in transfusing this patient with a universal donor than was attributable to her extreme anaemia—the unavoidable incompatibility between the donor's serum and the recipient's cells being assumed to be maximal in cases where the recipient's red count is very low—but that in practice we could not tell what might happen. It was also advised that the transfusion be limited to 150 c.cm. of blood given very slowly.

Transfusion was carried out with complete success, the only reaction being a very slight rigor. We suggested that special watch should be kept for haemoglobinuria; however this was entirely absent. The presence of auto-agglutinins was thus no bar to a successful transfusion, though we should not in the circumstances have been prepared to take the risk of neglecting the auto-agglutination phenomena by recommending the transfusion of such a case with blood of the same group. This comment would not apply to group O recipients. In all cases where abnormal agglutinins are present the donors selected should be of group O and very careful cross testing is required.

Conclusions

1. In a case of grave anaemia the blood was found to be of group AB type with normal cell reactions and abnormal serum reactions,

2. Auto-agglutination in the cold was also present.

3. Removal of the auto-agglutinins by incubation with the patient's own cells at refrigerator temperatures removed the abnormality from the serum.

4. The apparent abnormality of the blood group is thus due to the addition of the auto-agglutinin effect to the normal reactions of the serum.

5. The presence of auto-agglutinins is not necessarily any bar to a successful blood transfusion, though only group O donors are admissible in such cases, and careful cross testing is essential.

6. As this patient has a history of kala-azar and is at present suffering from syphilis, this case is no exception to the usual experience that auto-agglutinins only appear in human serum during grave disturbances of health.

Acknowledgments

We are greatly indebted to Lieut.-Colonel A. H. Proctor, D.S.O., I.M.S., Surgeon Superintendent, Presidency General Hospital, Calcutta, for the opportunity of examining this blood, and to Dr. S. J. G. Nairn, Resident Surgeon of the hospital, for the use of his clinical notes.

DIET AS A POSSIBLE FACTOR IN THE CAUSATION OF STONE IN THE BLADDER IN THE PUNJAB

By SIR JOHN MEGAW, K.C.I.E., K.H.P., M.B., B.Ch.

MAJOR-GENERAL, I.M.S.

Director-General, Indian Medical Service, Delhi

THIS note deals with an attempt which was made to find out whether the incidence of stone in the bladder in the three chief communities of the Punjab would throw any light on the relationship between diet and stone formation. The important work of Col. McCarrison and other investigators strongly suggests that diet is a factor of great importance in connection with stone formation.

The data contained in the table were supplied by the civil surgeons of the Punjab; I am much indebted to them and to the former Inspector-General of Civil Hospitals, Col. Mackenzie, C.I.E., I.M.S., for all the trouble they have taken in obtaining the information which was asked for.

It will be seen that the incidence of stone is much lower in Sikhs than in the other two communities, being only half that in Hindus

and less than one-third of that in Muslims. The figures for cataract were obtained partly to serve as controls and partly to find out whether any significant differences existed in the prevalence of cataract among the members of the three communities. The percentage incidence of cataract is almost the same in Muslims and Sikhs, while that for Hindus is somewhat lower. If, however, the large figures for the Mathra Das Dispensary of Moga had been included, there would actually have been a higher incidence in Hindus than in Muslims, so that there is no evidence of any significant difference in the incidence of cataract among the three communities. The figures for Moga had to be excluded partly because Sikhs were not shown separately in the returns, having been grouped among the Hindus and partly because patients go to Moga from all parts of India.

An attempt was made to find out from the civil surgeon whether the diets of the three communities differed in any important respects, but the evidence on this subject does not justify the expression of any clear-cut statement, except on broad general lines. It is generally agreed (a) that on the whole Hindus take more milk, fruits and vegetables than Muslims, (b) that Muslims eat much more meat than Hindus, (c) that the Sikhs have a more varied and more nutritious diet than either of the two other communities and that on the average they drink more milk than do the members of the other communities. According to Col. McCay the average daily diet of adult Sikhs consists of—milk 16 ounces, wheat 24 ounces, butter 2 ounces, dal 3 ounces, vegetables 6 ounces, and meat 4 ounces. This is certainly a much better diet scale than that of the other communities, it contains notably more milk than the diet of the Muslims, more meat and milk than that of the Hindus. With regard to the amount of wheat that is eaten by the people of the three communities it is impossible to make any dogmatic statement.

The figures are of some interest, they suggest that the tendency to stone formation is less among people who eat a well-balanced and nutritious diet containing a large proportion of milk than among those whose diets are unsatisfactory in these respects. It would be unjustifiable to claim that the data demonstrate a definite relationship between special kinds of food and the formation of stone, but at any rate they suggest that valuable information on the subject might be obtained by making a detailed enquiry in the Punjab.

A factor which may be of importance is the Ramzan fast. For a month in each year all strict Musalmans observe a strict fast from sunrise to sunset; the deprivation of water, especially when the fast falls in the hot dry season, must cause a high degree of temporary dehydration and concentration of the urine.

CYTOLOGICAL STUDIES OF THE BLOOD AND TISSUES IN KALA-AZAR AND ASSOCIATED CONDITIONS

Part IV.

THE LARGE MONONUCLEAR CELLS IN MONKEY MALARIA

By K. V. KRISHNAN, M.B., M.R.C.P.E., D.B. (Lond.), D.Sc.,

JEMADAR CHIRANJI LAL, I.M.D.

and

L. EVERARD NAPIER, M.R.C.S., L.R.C.P.

Officer-in-charge, Kala-Azar Enquiry, Indian Research Fund Association

(From the Calcutta School of Tropical Medicine)

IN a previous paper we recorded the results of a preliminary investigation on the large mononuclear changes in the blood of human beings suffering from malaria (Napier, Krishnan and Lal, 1932). In that paper, on account of the small number of cases studied, we could draw only tentative conclusions regarding the functional rôle of the two types of large mononuclear cells in malarial immunity. While that investigation was in progress Napier and Campbell (1932) found a plasmodium in the blood of a monkey, *Macaca irus* (*Macacus cynomolgus*), which while producing only a chronic type of low-grade infection in members of this species gave rise to a rapidly-progressive and fatal form of infection in monkeys belonging to the species *Macaca mulatta* (*Macacus rhesus*). This gave us an opportunity to investigate in detail the qualitative and quantitative changes in the large mononuclear cells of the blood in monkey malaria, from the very commencement of infection to its termination, and to obtain more conclusive data regarding the function of the large mononuclear cells. Altogether we studied supravital preparations of blood obtained from eighteen infected monkeys at different stages during the progress of infection and of immunity. In this paper we have presented some of our observations; these appear to us to show that histiocytes and monocytes are jointly responsible for the overcoming of the malarial infection, but that they differ from one another in the manner in which they produce their effect.

Source of material

In order to obtain samples of blood from infected monkeys at all possible stages of infection and immunity the following course was adopted. Twelve *M. mulatta* and six *M. irus* monkeys in a healthy state were obtained and before infecting them with the plasmodium the blood of each was examined a few times in order to make sure that all were free from parasites and to obtain a true normal picture of the blood cell elements, particularly of the large mononuclear group. Each animal was then given approximately the same dose of infective material subcutaneously (about 5 drops of heavily-parasitised blood from a *mulatta* monkey, mixed with 10 drops of citrated saline),

and thereafter a daily examination of its peripheral blood was made for the presence of parasites, and for ascertaining the large mononuclear changes.

Out of the 12 *mulatta* monkeys inoculated one proved refractory and 11 developed infections after periods varying from 3 to 12 days; their pre-patent* periods were 3, 3, 4, 5, 5, 5, 5, 6, 8, 9, and 12 days, respectively. Of the 11 infected monkeys, four were given no treatment and their infection was allowed to run its natural course; three of these died within six days of the commencement of the patent* period. The parasite count showed a rapid and progressive rise until it reached nearly a million per cubic millimetre of blood before death. The fourth monkey showed a tendency towards natural cure and survived for a period of 32 days without treatment. During this period the parasite counts showed great fluctuations and on the 25th day no parasite could be found. For the next 7 days all examinations were negative, but on the 32nd day its condition suddenly became worse and its blood again showed a few parasites. Administration of quinine helped it to tide over the crisis and ultimately to get rid of the infection. The remaining 7 monkeys were all given treatment as soon as their general condition became bad or the parasite rate rose to about half a million per cubic millimetre of blood, which number was generally reached within 3 or 4 days of the commencement of the patent period of infection. In this treated group one died suddenly, 51 days after infection and 30 days after completion of treatment that had been continued until all the parasites in its peripheral blood had completely disappeared and the animal had received a total of about 15 grains of quinine. For nearly a month preceding its death its blood had been free from parasites, but after death post-mortem examination of spleen and liver smears showed a fair number of developmental forms of the parasite. In four of the remaining six treated monkeys, quinine has so far had only the effect of preventing fatal issue in the acute type of infection and converting it into a chronic relapsing type. During the past four months these monkeys have had several relapses after latent periods varying in duration from a few days to a few weeks. Only two of the treated monkeys, which had heavy doses of quinine over a long period, have been cured so far. In these not only have we failed to find parasites

* We are using the words *patent* and *pre-patent* at the risk of offending purist readers, because we know no other single words that express so well the ideas we wish to convey; the *pre-patent* period is the period between the inoculation of the virus and the appearance of the parasites in the peripheral blood (in sufficient numbers to be demonstrated by the methods at our disposal), and the *patent* period is the period during which parasites can be found in the peripheral blood. We claim no originality, and we append this explanatory note only because the words are not in common use in this country.

after repeated examination of their peripheral blood, but inoculation of the blood into healthy monkeys has also failed to produce infection.

The one 'refractory' monkey was given two more heavy doses of infective material at fortnightly intervals and eventually it developed malaria five days after the third massive dose of infected material (table IX).

As regards the 6 *irus* monkeys all but one became infected, the pre-patent periods of these five being 6, 7, 7, 11 and 36 days, respectively. These remained untreated for a period of two months and during this period they all showed a relapsing type of low-grade infection with the parasite count at no time reaching a maximum of more than a few thousands. After several relapses two of the monkeys were given quinine; this resulted in the prompt disappearance of the parasites and so far they have not relapsed. Of the three others remaining untreated, one died, probably of some intercurrent disease, post-mortem examinations of spleen and liver smears showing a few parasites, and the remaining two monkeys showed a low-grade relapsing type of infection for nearly 3 months. Examination of these monkeys after the lapse of six months revealed that both of them had successfully got rid of the infection and that they were resistant to re-infection. Three attempts to infect the refractory monkey proved completely futile.

From the above summary it will be evident that the material for the study of the mononuclear changes was obtained from a number of different monkeys during a great variety of phases of infection and immunity.

Technique

Supra-vital preparations of blood as well as fixed films, stained by Giemsa's method, were studied. The technique of supra-vital staining was the same as that described by us in a previous paper (Napier, Krishnan and Chiranjilal, 1932a). Total counts of the leucocytes, and parasites were also obtained. In order to avoid errors due to sampling and the personal factor in the counts, we made at the least two preparations on each occasion and recorded the average of the counts made by two observers, working independently of one another. For the purpose of the differential counts the number of leucocytes counted by each worker in any one slide was never less than 100.

Results

Though in a few instances we were able to follow the blood-cell changes in an individual monkey as the infection passed through its various stages of invasion and culmination, or latency and regression, the gaps which necessarily occurred in such records detract from the value of the picture they present, and we have thought it best to group and give in separate tables the counts obtained at different clinical stages of infection and recovery, irrespective of

the individuals from which the blood was obtained, only showing separately the counts in the two different species of monkey. These counts are shown in tables I to IX.

The following is a brief summary of the findings as shown in each table:—

Table I shows that the total large mononuclear count in normal *mulatta* and *irus* monkeys is about 4 per cent. and is composed chiefly of monocytes. There appears to be no difference in the counts in the normals of the two species with regard to this cell type.

Table II shows that during the pre-patent period of infection there is little or no change in the total large mononuclear count of the *mulatta* monkey, but that there is perhaps a slight tendency for the intermediate forms and the histiocytes to increase at the expense of the monocytes. In *irus* monkey on the other hand there is a definite increase in the total number of large mononuclear cells brought about by an increase of intermediate forms and histiocytes, the monocyte count showing little change.

Table III shows that on the first day of the patent period in the *mulatta* monkey there is a distinct rise in the number of total large mononuclear leucocytes and that this increase is due chiefly to a rise in the number of histiocytes and intermediate forms. The monocytes show a distinct fall. The *irus* monkeys show under similar circumstances a more marked increase in the large mononuclear cells and here the rise is due to increase in all three forms.

Table IV shows that in both species of monkey about the middle of the patent period when parasites are fairly numerous and the animals not too ill, the large mononuclear count is distinctly high and that this increase is brought about by a rise in the number of intermediate forms and histiocytes, the monocyte count showing very little change.

Table V shows that when the *mulatta* monkey is looking very ill as a result of the infection and on account of a failure of its immunity response there occurs a fall in the total large mononuclear count, the fall being attributable chiefly to a decrease of the histiocytes and to a smaller extent of the monocytes.

Table VI shows that a day or two before death in the *mulatta* monkey there is a tremendous drop in the total large mononuclear count and this is brought about by a decrease in all forms, particularly monocytes.

Table VII shows that administration of quinine is followed by an increase of all forms of large mononuclears and specially of histiocytes and intermediate forms. This change is best seen in the *irus* species.

Table VIII shows the similarity between the cytological changes taking place in animals with a tendency for natural cure and those that are recovering as a result of treatment with quinine. Here again the rise in histiocytes and intermediate forms are most marked.

Table IX shows that in resistant monkeys following the inoculation of infective material there generally occurs a prompt and marked mobilisation of the large mononuclear cells in the peripheral circulation.

Table A. A summary of tables I to VIII.

The changes in the percentages of the different large mononuclear cells in the peripheral blood

The changes which occur in the large mononuclear counts during the various phases of the malarial attack can be seen in tables I to VIII, at the end of the paper; they are summarized in table A and shown in graphic form

TABLE A

Showing the mean percentage distribution of the different types of large mononuclear cells in the blood of normal monkeys and of monkeys in different stages of a malarial attack; a summary of tables I to VIII

	Table from which means are taken	Stage of infection	Number of observations on which based	Total leucocytes	Total large mononuclears	Monocytes	Intermediates	Histiocytes

	VIII	Natural recovery	11	18,041	14.5	5.6	5.6	3.3

in chart I. In *Macaca mulatta* monkeys the normal appears to be about 4.4 per cent. of

CHART I

the total white cells. In the early patent stage of infection there is a distinct rise in the percentage of large mononuclears and this rise is even more marked later, as the parasite count rises. The fate of the animal now appears to depend on whether the mononuclear count is maintained or not; if there is a further rise the animal recovers and the infection disappears or passes into a latent stage, but if the mononuclear response fails and the count falls the infection gets the upper hand; at this stage if the failure is not too complete quinine administration will often result in a sharp mononuclear rise and will save the animal. In *Macaca irus*, in which species recovery is the rule, the mononuclear rise occurs earlier; the administration of quinine causes a further very marked mononuclear response which is usually followed by complete disappearance of the parasites. If no quinine is given then the infection usually passes into the latent stage and a moderately-high large-mononuclear count will be maintained (chart II).

The behaviour of each of the three types of cell in the mononuclear group is not the same. We will consider the monocytes first; in the pre-patent and early patent stages there is an apparent fall which is almost entirely compensated for by a rise in the number of the intermediate forms. This suggests that some of the monocytes have taken on an increased phagocytic function which qualifies them to be classed as intermediate forms. If we consider the monocytes and intermediate forms together, which whilst considering the question of the monocytic response seems justifiable, as there is little doubt that they have a common origin, we see that in the *M. mulatta* series (chart

CHART II

The large-mono-nuclear response at various stages of a malarial attack in a *M. irus* monkey. See letter-press to chart I.

III) there is no sign of any rise in the early stages of the infection; there is in fact a slight though insignificant fall. At a later stage of

CHART III

The monoocyte response at various stages of a malarial attack. See letter-press to chart I.

the infection, when possibly a destruction of a certain number of parasites has provided the necessary stimulus, there is a sharp rise; after this the monoocyte curve follows the general large mononuclear curve. In monkeys refractory to infection there is an early monoocyte response to the dose of morbid material, which appears to prevent infection occurring (table IX and chart V).

CHART V

The large-mononuclear response to inoculation with morbid material in a *M. mulatta* monkey which at first proved refractory to malarial infection. The ordinates are the large mononuclear percentages of individual differential white counts; the abscissæ are arbitrarily spaced.

On the other hand the histiocytes which are not normally present in the peripheral blood make their first appearance at an early date in the infection, some time before the monocytes start to rise, they then follow the general mononuclear curve (chart IV). However, the sharp

CHART IV

The histiocyte response at various stages of a malarial attack. See letter-press to chart I.

rise (table VIII) which is associated with recovery of the animal is not maintained as in the case of the monocytes and when the infection passes into the latent phase the histiocytes drop to 1 or 2 per cent. (This is not shown in either the tables or the charts.)

Function of the large mononuclear cells

As far as we are aware very little work has been done to determine whether or not the two

types of large mononuclear cell, monocytes and histiocytes, are different in function. During the present investigation therefore in addition to noting the quantitative changes, already recorded above, we took particular pains to study the behaviour of the several types of mononuclear cells in our supra-vital preparations, hoping thereby to ascertain how far their functions, as regards resistance and cure in malaria, can be said to be similar or dissimilar. Our findings and views are discussed below.

Histiocytes

Some of the earlier workers on malaria have suggested that the histiocytes are probably the phagocytes chiefly responsible for the destruction of the malarial parasites (*vide* Napier, Krishnan and Lal, 1932). The results of this investigation show that the histiocytes are undoubtedly the best phagocytes. We have repeatedly seen them in supra-vital preparations containing a variety of objects, such as red cells—infected and uninfected, pigment, platelets and cell debris of various sorts, as well as a large amount of neutral red (*vide* plate). This leaves no doubt whatsoever regarding their phagocytic capacity. When, however, we come to consider whether the histiocytes take up living malarial parasites, and, if so, whether they kill and digest them as well, we must admit that we do not possess sufficient evidence to justify the expression of a definite opinion. We attempted to study the powers of destruction of the histiocytes at

various stages of malarial infection by watching the changes taking place in the ingested parasites within living histiocytes for varying periods of time. We also noticed their method of disposal of the parasites after the administration of quinine and other anti-malarial remedies, and saw that whereas in the early stages of infection the histiocytes contain mostly pigment, or occasionally a red cell, that later, when infection is progressing, they are seen with pigment, parasites and parasite-infected red cells showing undoubted evidence of varying degrees of destruction and digestion, that still later, when the infection is well established and severe, and the animal is losing ground, the histiocytes again contain fewer parasites and more pigment, some of the parasites contained appearing perfectly healthy and showing no evidence of degeneration (*vide* plate, fig. 2), and that finally as the infection is reaching a fatal termination the histiocytes' powers of phagocytosis and destruction, as well as their number (*vide supra*), are found to be at a minimum. Even the amount of neutral red taken up by these cells is sometimes very small at this stage. If, however, either on account of increased natural resistance or of the administration of quinine or other specific drugs, the animal gains the upper hand, then accompanying the sudden and sharp rise in the number of histiocytes (*vide supra*) there is a marked heightening of the phagocytic and destructive powers of the majority of these cells. From these observations we are led to infer that the histiocytes under certain conditions, though not always, are capable of taking up living parasites, and killing and digesting them; biochemical conditions within the host possibly determine whether or not such an action takes place. We have evidence that under certain adverse conditions these cells may not have the power to destroy the parasites but require the help of other factors before their destructive powers can be brought into play. Even so the importance of histiocytes in the cure of malaria is unquestionable. The mere fact that the histiocytes are helpful in the phagocytosis and removal from the circulating blood of a large number of infected red cells to the internal organs for the purpose of effective destruction, is in itself sufficient to give the histiocytes an important place in malarial immunity, for such an action will form an effective check in the schizogony cycle.

It is generally accepted that the histiocyte, whether in the blood or in the tissues, is primarily concerned with the disposal of damaged and degenerated red blood corpuscles. Naturally therefore it will ingest any red cell that is damaged, irrespective of the cause of damage. There is every reason to believe that the entry and development of the malarial parasites within the red cells damages these cells, which are therefore engulfed by the histiocytes. It is possible that the histiocytes take

them up not for the destruction of the parasites that they contain but for the disposal of damaged red cells themselves. The destruction of the parasite when it takes place may thus be purely circumstantial. It is unnecessary to discuss whether it is brought about by the unsuitability of the condition within the cell interior or by an inherent lytic capacity possessed by the cell. Whatever it may be all evidence supports the view that some of the parasites at any rate are destroyed by the histiocytes.

The function of the intermediate forms

In our previous communication we suggested that the intermediate forms possibly originated from monocytes in response to stimuli demanding more phagocytic cells but that with regard to function they should be treated as young and active histiocytes because of their more marked similarity to these than to the monocytes. We still hold this view and consider that as far as function is concerned these cells should be classified with the histiocytes. Although in the intermediate forms one does not find the same variety of ingested material within their cytoplasm as in the histiocytes, under the stress of a suitable stimulus the former appear to be as efficient phagocytes as the latter though perhaps more selective in their choice. We think they are chiefly concerned with the phagocytosis of free or living parasites, for, although they have been seen containing infected red cells, they do not show them quite as frequently as the histiocytes. They are more often found with pigment and debris, and this we think is not because they take up only pigment but rather because they are capable of digesting the engulfed parasites with greater rapidity than are the histiocytes. We have on a few occasions actually seen these cells taking up into their cytoplasm what appeared to us to be malarial parasites. The process of lysis was very rapid and it was over before we could make a *camera-lucida* drawing of what we saw. All we could see in these cells after the lapse of some seconds was particles of pigment (*vide* plate, fig. 4). It appeared as if the cell on ingesting the parasite segregated it at the *hof* of the nucleus where there seemed to be a distinct round vacuole-like area. Here everything that was engulfed was isolated and lysed, and the black pigment or debris resulting from it sent out to the periphery of the cell. On one occasion we saw a cell actively progressing towards a collection of infected red cells in a zig-zag way (*vide* plate, fig. 10); we saw within its cytoplasm pigment and certain other bodies resembling fragments of parasites; as it reached the collection of infected red cells it became sluggish and all these cells adhered to it. Nothing further was noticed even though we watched it for nearly half an hour subsequently. From this and other observations we think that the intermediate forms are not only efficient phagocytes (*sensu restricto*) of the malarial

parasites, but are also responsible for their destruction.

Function of monocytes

The absence of any debris, other than a few particles of malarial pigment, from these cells suggests that the true monocytes are poor phagocytes as compared with the histiocytes. (Admittedly this might indicate that they digest the parasites so quickly that they are never seen to contain them in supra-vital-stained preparations; we do not however take this view.) Thus, the claim for the function of monocytes in malarial immunity is dependent on the evidence of their response to the invasion of the parasites which we have clearly demonstrated (*vide supra*) and—if we accept the suggestion that the intermediate forms arise from them—on their ability to assume phagocytic powers under special conditions, also, in the absence of a good monocyte response, on the failure of a histiocyte increase alone to bring about an appreciable reduction in the parasite count. Though the figures in the other tables (I to VIII) do not bring out the fact very clearly we have other evidence which indicates that a continued high monocyte response, as is seen in certain monkeys in which the infection becomes chronic (or latent), even in the absence of a high histiocyte count, will control the infection and prevent any increase in parasites. Table IX demonstrates the importance of this monocyte response in malarial immunity very clearly.

We therefore assume that the action of monocytes is an indirect one, and that the increase in the number of monocytes is associated with some change in the plasma which produces a reduction in the number of parasites. What exactly is the nature of the change in the plasma, or how it produces this effect, we will not attempt to suggest.

We have gained an impression—which subsequent investigations may support or disprove—that there is slowing down of the sexual cycle when this monocytosis is evident. In any case, there is, we think, ample evidence that monocytosis is an important factor both in resistance and cure.

Conclusions

It is apparent from the above-recorded observations that each of the three types of mononuclear cell plays a part in malarial immunity. The function of the histiocyte is primarily the removal of damaged red cells from the peripheral blood. In a malarial attack it is the first cell to be stimulated—the stimulus probably coming from the red-blood-cell debris resulting from the early schizogony cycles. As more and more red cells are destroyed the histiocyte percentage rises, and it falls again when the infection becomes latent and there is little blood destruction occurring. In those cases in which the infection gains the upper hand and there is a general failure of cellular response,

the histiocyte percentage also falls. The destruction of malarial parasites by these cells may be only incidental, but the number they remove from the circulation must be considerable.

The intermediate type is the next cell to be stimulated and here again it may be the demand for the removal of cell debris which has called for their presence in large numbers in the peripheral blood, or has stimulated monocytes to assume increased phagocytic activity. These cells destroy a large number of parasites, their lytic properties seem to be much greater than those of the histiocytes, as the parasites they contain always appear to be in an advanced stage of disintegration.

The monocyte is the last cell to be stimulated and we have suggested that the origin of this stimulus is the destruction of a number of malarial parasites in the early stages of the infection by the reticulo-endothelial cells, the histiocytes. As long as there are any malarial parasites present in the body the monocyte count will remain high, except in those cases in which there is a general failure of cellular response which precedes the death of the animal, and conversely as long as the monocyte count remains high the malarial infection will not get the upper hand. The action of the true monocyte in malarial immunity is probably indirect and is associated with some humoral change in the serum which limits the multiplication of the parasites in the body.

There is considerable evidence to show that in malarial infection quinine acts partly by stimulating the normal processes of cellular immunity.

Summary

1. Over 300 specimens of blood from 18 monkeys (12 *Macacus mulatta* and 6 *M. irus*) were studied with the help of the supra-vital staining technique.

2. The large mononuclear cells present in the blood during the pre-patent, patent, latent and secondary patent periods, as well as the period following the administration of quinine, were studied and classified as either monocyte, histiocyte or an intermediate type.

3. From the results obtained, the probable function of monocytes and histiocytes in the cure of malaria is discussed, and certain tentative conclusions are arrived at.

4. *Camera-lucida* drawings of some of the typical monocytes and histiocytes found in the peripheral blood of monkeys in the course of the present investigation are given in a coloured plate.

Acknowledgment

Our thanks are due to Mr. Mullick for the patience and care he exercised in the preparation of the coloured plate.

All the blood counts in this series were done by the first two workers; all three workers are responsible for the presentation of the results and for the conclusions.

DESCRIPTION OF PLATE I

Cytological studies of the blood and tissues in kala-azar and associated conditions.

PARTS IV AND V.

Figures 1 to 16 in this plate are cells from supra-vitally stained preparations of the blood of monkeys suffering from malaria, and figures 17 to 27 are cells from the peripheral blood and spleen of human kala-azar cases. The drawings were made from *camera-lucida* sketches; in order to ensure correct colouring, fresh microscopic specimens were used as a guide.

PART IV. *The large mononuclear cells in monkey malaria.*

1. A histiocyte showing a number of infected red cells and a disintegrating malarial parasite.
2. A histiocyte with pigment and malarial parasite.
3. A histiocyte with malarial pigment.
- 4, 5 and 6. Intermediate forms with malarial pigment. No. 4 in addition shows malarial parasites.
7. A histiocyte showing a few mitochondria and large neutral-red vacuoles.
- 8 and 9. Histiocytes with malarial pigment. No. 8 shows also a few mitochondria.
10. An intermediate form that was seen actively moving towards a collection of infected red cells. Note the round area at the *hof* of the nucleus. This and the mitochondria led us to classify this cell as an intermediate form, though it is an unusually large one. It was in the vacuole-like area that the cell segregated the ingested substances first, and, later, after digesting them, sent them to the periphery.
- 11 and 12. Monocytes with malarial pigment.
13. A monocyte in the process of cell division.
- 14, 15 and 16. Forms intermediate between monocytes and our intermediate forms, classified as monocytes, showing malarial pigment.

PART V. *The large mononuclear cells in the peripheral and in the spleen blood in kala-azar.*

17. A histiocyte from spleen with many *Leishmania donovani*—although actively phagocytic it shows a preference for parasites only.
- 18 to 21. Histiocytes from spleen showing *L. donovani*, neutral-red vacuoles and red blood cells. No. 19 in addition shows an ingested nucleus. All these cells were actually seen ingesting the red cells and *Leishmania* that were present in their immediate neighbourhood.
- 22 to 24. Histiocytes from peripheral blood. No. 24 was the common type seen in kala-azar and it is peculiar in that the distribution of neutral red is all round the nucleus instead of in the area in front of it.
- 25 and 26. Monocytes from peripheral blood. In addition to the rosette a tiny vacuole or two of neutral red is also present.
27. A monocyte from the spleen.

PLATE I.

CYTOLOGICAL STUDIES OF THE BLOOD AND TISSUES IN KALA-AZAR AND ASSOCIATED CONDITIONS

Part V.

THE LARGE MONONUCLEAR CELLS IN THE PERIPHERAL AND IN THE SPLEEN BLOOD IN KALA-AZAR.

By L. EVERARD NAPIER, M.R.C.S., L.R.C.P.

K. V. KRISHNAN, M.B., M.R.C.P.E., D.B. (Lond.), D.Sc.
and

JEMADAR CHIRANJI LAL, I.M.D.

(From the Kala-Azar Enquiry, Indian Research Fund Association, School of Tropical Medicine, Calcutta)

From time to time conflicting opinions have been expressed by different workers regarding the rôle of the phagocytic large mononuclear cells in kala-azar. Knowles (1920) suggested that the hyaline cells of the blood function as host cells rather than as destroyers of leishmania. Brahmaehari (1928) stated that the development of *clasmatocytes* is what one should aim at in the treatment of kala-azar, thereby presumably meaning that these cells are destructive, rather than protective, to leishmania. Cash and Hu (1927) as a result of their cytological studies on leishmania-infected hamsters came to the conclusion that increase of *clasmatocytes* favours multiplication of leishmania and helps in the distribution of the parasites to the different parts of the body. Krishnan (1932) from his studies of the leucocyte changes in human kala-azar, stated that the cells of the reticulo-endothelial system were responsible both for susceptibility and resistance, and that increase in the number of phagocytic cells without destructive powers favoured infection. From these references it will be clear that as yet no definite decision has been arrived at regarding the part played by the two different types of large mononuclear cell, the monocyte and the histiocyte, in kala-azar. As we are of opinion that a knowledge of the cellular and serological conditions favourable to invasion of leishmania would be of great value at the present stage of the kala-azar transmission problem, we investigated the cellular changes in the large mononuclear group in the blood and tissues of kala-azar cases with the help of the supra-vital staining technique.

The large mononuclear cells in the peripheral blood in kala-azar

The subjects of this study were kala-azar patients in the wards of the Carmichael Hospital for Tropical Diseases. They were all diagnosed as kala-azar by the demonstration of the parasite in their peripheral or spleen blood, either by direct examination of a stained smear or by cultural methods. The patients were mostly Indian adult males who had hitherto had no specific treatment for kala-azar. A few, including two of the patients who did not respond to treatment, had previously been treated for the disease and had relapsed, but none of these

had received any antimony injections for at least two months prior to the commencement of the present investigation of their blood cellular condition.

The treatment given was that which has for some time been adopted as the routine treatment for kala-azar in our hospital, namely, daily intravenous injections of neostibosan, commencing with a dose of 0.3 gramme and making 0.5 gramme the maximum: during part of the investigation only six doses were given, but later the total number was increased to eight. No difference was observed clinically, or otherwise, in the results obtained with these two different courses of treatment.

The supra-vital staining technique and the criteria for identification of the different cells are those which have already been described by the present writers in previous papers in this series. The large mononuclear cells were classified as monocytes (including the intermediate forms*) or histiocytes.

Altogether 322 samples of peripheral blood from 59 cases of kala-azar were studied. Of these 96 samples were obtained prior to treatment, 72 samples during treatment, and 154 samples from 1 to 4 weeks after completion of treatment.

For tabulation of the results, patients have been divided into two groups, those who did and those who did not improve clinically; and the latter group has again been divided, as far as after-treatment counts are concerned, into those cases in which there was a total leucocyte increase and those in which there was no such increase.

TABLE A
Patients that were successfully treated

Total leucocytes per c.mm.	Mean of counts	Probable error of mean	Range of counts
(i) Prior to treatment; 88 counts in 44 cases.			
Total leucocytes per c.mm.	3,620	± 112.27	2,000 to 6,000
Total large mononuclear percentage.	9.55	± 0.27	4 to 18
Monocyte percentage	3.85	± 0.16	1 to 8
Histiocyte percentage	5.69	± 0.22	2 to 10
Ratio M/H $\times 100$	73.61	± 5.26	14 to 350
(ii) At conclusion of course of injections; 46 counts in 46 cases.			
Total leucocytes per c.mm.	4,926	± 160.4	2,500 to 7,500
Total large mononuclear percentage.	8.38	± 0.24	5 to 13
Monocyte percentage	5.86	± 0.19	4 to 9
Histiocyte percentage	2.52	± 0.14	1 to 5
Ratio M/H $\times 100$	255.44	± 11.55	100 to 400

*Our reason for not differentiating between intermediate forms and monocytes in this series is that some of the counts were made at the beginning of these 'supra-vital' investigations, at a time when this differentiation was not made, so that, to bring all the counts into line, it was necessary to group the monocytes and intermediate forms together in the whole series.

TABLE A—concl'd

Total leucocytes per c.mm.	Mean of counts	Probable error of mean	Range of counts
(iii) 2 to 4 weeks after completion of treatment; 126 counts in 54 cases.			
Total leucocytes per c.mm.	7,040	± 155.25	3,100 to 12,500
Total large mononuclear percentage.	7.84	± 0.18	4 to 15
Monocyte percentage	6.15	± 0.17	3 to 12
Histiocyte percentage	1.69	± 0.07	1 to 5
Ratio M/H × 100	433.73	± 17.08	100 to 1,000

(iv) At time of discharge as cured; 16 counts in 16 cases.

Total leucocytes per c.mm.	5,025	± 344.29	3,000 to 7,500
Total large mononuclear percentage.	4.41	± 0.21	3 to 6
Monocyte percentage	4.41	± 0.21	3 to 6
Histiocyte percentage	0
Ratio M/H × 100

TABLE B

Patients that showed little or no improvement after treatment

Total leucocytes per c.mm.	Mean of counts	Probable error of mean	Range of counts
(i) Prior to treatment; 8 counts in 5 cases.			
Total leucocytes per c.mm.	3,275	± 185.33	2,500 to 4,000
Total large mononuclear percentage.	13.19	± 1.06	8 to 18
Monocyte percentage	4.32	± 0.43	3 to 6
Histiocyte percentage	8.87	± 0.97	5 to 12
Ratio M/H × 100	49.5	± 2.22	43 to 60

(ii) 1 to 4 weeks after completion of treatment in cases showing no increase of leucocytes; 26 counts in 3 cases.

Total leucocytes per c.mm.	3,638	± 130.58	2,500 to 5,000
Total large mononuclear percentage.	9.17	± 0.49	4 to 14
Monocyte percentage	3.64	± 0.29	2 to 7
Histiocyte percentage	5.53	± 0.39	2 to 10
Ratio M/H × 100	77.07	± 7.44	20 to 167

(iii) 1 to 4 weeks after completion of treatment in cases showing increase of total leucocytes; 12 counts in 2 cases.

Total leucocytes per c.mm.	7,200	± 162.77	6,300 to 8,100
Total large mononuclear percentage.	6.77	± 0.83	5 to 11
Monocyte percentage	1.49	± 0.66	1 to 2
Histiocyte percentage	5.28	± 0.54	3 to 9
Ratio M/H × 100	33.5	± 4.59	17 to 67

The results of the peripheral blood counts recorded above, bring out the following points:—

(1) In kala-azar there is a marked increase in the large mononuclear elements in the peripheral blood. This increase, as judged by the

mean of the observations, is slightly more marked in those cases which subsequently do not improve on treatment, but the deviation from the mean is a wide one and the difference is not large enough to make this observation one of prognostic significance.

The feature of this mononuclear increase is a marked histiocyte increase; these cells may number 12 per cent. of the total white count and are much more numerous in the cases with a bad prognosis. The monocyte/histiocyte ratio is nearly always below 1.

(2) With the commencement of specific treatment there occurs a distinct drop in the relative number of histiocytes and a rise in the number of monocytes. When the patient is progressing towards recovery these changes are very much more pronounced, and eventually the ratio of monocytes to histiocytes is completely reversed.

(3) If, however, treatment fails to bring about cure, neither the drop in histiocytes nor the rise in monocytes is noticeable.

(4) In all the cases of the first group, i.e., those which respond well to treatment, there is a marked increase in the total leucocyte count after treatment: in some of the cases of the other group there is also a leucocyte increase, but in these cases there is no reversal of the monocyte/histiocyte ratio. This seems to be an essential reaction for cure to be effected.

The large mononuclear cells in the spleen blood in kala-azar

Although usually a study of the peripheral blood gives a very good indication of the pathological and immunological changes taking place within the body, it was thought that it was important also to study the blood cellular changes taking place in an actual focus of infection such as the spleen. For, in this disease the characteristic change is an increase in the number of histiocytes and these are at times of enormous size, reaching 100 to 150 μ in diameter, and, being so large, are liable to be caught up in the lung capillaries and to get no chance to enter the peripheral circulation. Simpson (1922) and we ourselves have observed that in certain experimental rabbits proliferation of histiocytes resulting from repeated injections of colloidal dyes was not always accompanied by a corresponding increase of these cells in the peripheral blood. For this reason a study of the large mononuclear changes in the spleen was undertaken with the hope that it would furnish more conclusive and significant data than the study of the peripheral blood alone.

The blood was obtained from the spleen by the ordinary spleen puncture technique. A dry sterilized all-glass syringe was used, with the spleen puncture attachment (Napier, 1928) which enables the syringe to be manipulated with one hand while the other is used to control the spleen. Though it was not necessary to

maintain suction until blood appeared in the barrel of the syringe, it is necessary to withdraw and release the plunger rather more often than in ordinary routine puncture, as a large drop of blood is necessary for making two supra-vital preparations, whereas for diagnostic purposes the merest trace of blood is all that is necessary. This necessity to obtain a sufficiency of material prolongs and theoretically adds to the danger of the operation; we say 'theoretically' because we did not in these cases observe any increase in the post-spleen-puncture pain, which occurs occasionally and which can be attributed to local trauma, and in no case did more serious symptoms follow. For this reason we did not usually perform a spleen puncture more than twice and never more than three times on the same patient.

Incidentally, these spleen punctures demonstrated how infrequently one obtains what is usually described as 'spleen pulp' in this operation. In nine cases out of ten the material obtained spreads as quickly and as homogeneously under the coverslip as ordinary peripheral blood; it is in fact blood from the small sinusoidal spaces admixed with a very little fine cellular debris from the damaged spleen parenchyma. The blood which sometimes rushes into the syringe during a spleen puncture is from one of the larger splenic venous spaces. In either case the cellular composition of the blood is different from that of the peripheral blood which has subsequently passed through at least two sets of capillaries. The little granules of pulp which one sees in spleen-puncture material and which some writers have described as the *sine qua non* of a good spleen puncture are usually the result of an error in technique, either leaving some antiseptic in the barrel which coagulates the blood, or delaying too long before expressing the blood, which clots unusually rapidly.

A few preliminary experiments with spleen puncture material showed us that certain modifications in the usual procedure would have to be adopted before adequate data could be obtained from a study of it. First of all, on account of the very small amount of spleen blood that was generally obtainable by puncture, it was not possible to do a quantitative estimation of the white cells; even in the few instances where there was sufficient blood, whilst the supra-vital preparations were being made, the blood usually clotted in the syringe and thus became useless for cell enumeration. Secondly, when more than one puncture was done on the same patient on the same occasion—a practice that could only be adopted in certain cases—and cell counts performed on the different samples, it was noticed that very varying results were obtained. It is natural that there should be considerable discrepancies in samples taken from the small splenic sinuses, and from large venous spaces; the differences were at times so considerable that we were

convinced that total counts were valueless; on two or three occasions the point of the needle had obviously rested in a Malpighian corpuscle as the whole preparation was swamped by small lymphocytes; such preparations were discarded. With regard to the large mononuclear cells, however, the ratio between the monocytes and the histiocytes remained fairly constant in all the samples, and was not subject to any appreciable sampling error. Therefore, we decided to record our observations as variations in the ratio between these two cells; this nearly always corresponds closely with the ratio in the peripheral blood.

We made not less than two supra-vital preparations from each specimen of puncture material, counted all the large mononuclear cells in each, and from that calculated the number of monocytes and histiocytes present in 50 microscopic fields (the last procedure was adopted to facilitate statistical calculation). By this means we hoped to obtain not only a correct idea of the variation in the ratio of the two types of mononuclear cell, but also a rough idea of the quantitative changes in the total large mononuclear cells. Side by side with these examinations, fixed films of spleen blood were stained by Giemsa's stain and the number of parasites present in them estimated and grouped as +, ++, or ++++. This enabled us to correlate the cellular changes with increase or decrease of parasites.

The coloured plate, figures 17–27, shows the various cell types seen in the peripheral and spleen blood.

Altogether 59 samples of spleen puncture material were obtained in 32 cases of kala-azar. The patients were amongst those whose peripheral blood counts were made (*vide supra*). It was not possible to perform spleen puncture as often as we should have liked, as the condition of the patient had to be taken into consideration. It was therefore only in a few cases that we were able to follow up the cellular changes by punctures at the three different stages of the disease. In the majority of cases puncture was done only once at some distinct stage of infection or of recovery. Of the 59 samples examined 26 were from cases prior to treatment, 12 from cases during treatment, and 21 from cases after completion of treatment. The results obtained are given in the tables below.

The counts normally fall into three groups, *before*, *during*, and *after* treatment. There are a number of ways in which the untreated patients could be grouped, according to the acuteness of the illness, according to the length of duration of the disease, according to the size of the spleen, or according to the number of parasites present in the spleen blood. There is of course a considerable though not a complete correlation between the duration of the disease and the size of the spleen, but we found little correlation

between either these or the acuteness of the illness, and the cellular reaction; on the other hand we found a considerable correlation between the number of parasites and the cellular reaction, so that we divided our cases into two groups according to whether there were few or abundant parasites in the spleen puncture smears. Our criterion was whether there were more or less than one parasite *per field*; there was usually a sharp differentiation between the two groups of cases. It will be seen that the difference between the counts in these two groups is significant from a mathematical standpoint.

Again some patients react well clinically to treatment, others do not. We have therefore divided the treated patients into two groups according to their response to treatment, judged on clinical standards, *i.e.*, the absence of fever and the reduction in the size of the spleen. Patients of the latter group are comparatively rare but we have included as many as possible; the 8 counts were obtained from 3 such patients.

The tables are self explanatory.

The conclusions drawn from them can be summarized as follows:—

That in untreated kala-azar the monocyte/histiocyte ratio is low, always below 1 and in extreme cases below 0.1, and that it varies inversely with the intensity of the infection as demonstrated by the number of parasites in a smear.

That under treatment the monocyte/histiocyte ratio steadily increases, *pari passu* with the disappearance of the parasites and the clinical progress of the patient towards recovery; in the two extreme groups the mean ratio has undergone a 15-fold increase.

That when the patient does not improve clinically the monocyte/histiocyte ratio remains low and unchanged.

Discussion

The characteristic histological reaction in kala-azar is a marked increase of tissue histio-

TABLE C

Cellular changes in the large mononuclear group in the spleen blood in kala-azar : summary of tables I to V

Table	Group	Number of observations	MEAN OF THE			Probable error
			Numbers of monocytes in 50 fields	Numbers of histiocytes in 50 fields	Ratios M/H $\times 100$	
I	Untreated cases; few parasites.	10	7.0	11.3	62.72	± 4.04
II	Untreated cases; many parasites.	16	7.25	22.75	36.05	± 2.38
III	At end of course of injections; few parasites.	14	8.7	9.6	114.07	± 12.91
IV	Some weeks after successful treatment; no parasites.	11	19.7	4.66	507.87	± 30.50
V	Some weeks after unsuccessful treatment; few parasites.	8	6.0	18.9	35.86	± 5.07

TABLE D

Statistical analysis and comparison of different groups

Groups compared	Difference between the means of the two groups	Probable error of the difference	REMARKS
I & II	26.67	± 4.69	Significant.
I & III	51.35	± 13.52	Almost significant.
I & IV	445.15	± 30.75	Certainly significant.
II & IV	471.82	± 30.59	Certainly significant.
II & V	0.19	± 5.41	Not significant.

cytes at the various foci of infection; these foci are in many parts of the body wherever reticulo-endothelial cells are to be found, but most characteristically in the spleen. It is generally accepted that this increase in the number of histiocytes is caused by local multiplication, but the evidence of this is incomplete. We have shown above that together with this local aggregation of tissue histiocytes there is an increase in the number of histiocytes in the blood in the sinusoidal spaces of that reticulo-endothelial sponge, the spleen. Some of these histiocytes find their way into the general blood stream and the smallest of them eventually reach the peripheral blood where, we have also shown, they are to be found in relatively large

numbers, both parasitized and unparasitized. The immediate result of treatment is to reduce the focal aggregation of tissue histiocytes (this is reflected clinically by an early reduction in the size of the spleen); from our cytological studies we have no evidence of the fate of these cells. The evidence that they are carried away in the blood is lacking, as we have never noticed even a temporary increase of these cells in either the spleen or peripheral blood; on the contrary, there was an early marked decrease in the histiocytes of the spleen blood, as well as of peripheral blood. The assumption is therefore that local disintegration occurs. Together with this histiocyte decrease there is a monocyte increase; this is equally apparent in both the spleen and the peripheral blood.

To summarize, it appears that the characteristic reaction to leishmania infection is a histiocytosis, both focally and in the peripheral blood, and that the characteristic cellular reaction of successful immunity response is a monocytosis. The monocyte is not a very active phagocyte, so that we must conclude that the increase in the numbers of this cell in the blood is associated with a specific humoral reaction.

Observations bearing on the relationship of kala-azar and malaria

In both the blood and the tissue histiocytes there is little sign of 'digestion' of the leishmania and on the contrary there is evidence of free multiplication. This reaction of the host is therefore not in any way an immunity response but is probably a non-specific, purely cellular reaction to the presence of foreign bodies, and we know from clinical experience that there is little tendency, when a visceral infection is once established, for spontaneous recovery to take place without the intervention of some severe infection, such as pneumonia.

Furthermore, it seems quite possible that the histiocyte proliferation which occurs during a malarial attack (see previous papers in this series) would tend to disseminate and provide suitable nidi for a hitherto localized leishmania infection.

On the other hand we have shown that the histiocyte is capable of phagocytosing and destroying malarial parasites contained in red blood cells and we have suggested that such action might check a malarial infection. There is considerable evidence that this histiocyte reaction is a non-specific one. Thus the histiocyte response which occurs in kala-azar may be the factor responsible for keeping down the malarial infection in a kala-azar patient. (It is an indisputable fact and one to which the senior writer has repeatedly drawn attention that malarial parasites are rarely found in the blood of a kala-azar patient, but that again and again when the kala-azar is cured a typical clinical attack of malaria, with parasites in the peripheral blood, occurs.) It might then be argued, if a monocytosis is the characteristic

cellular reaction associated with successful immunity response, why does not the monocytosis, which is associated with a cure in kala-azar and is maintained for some considerable time, check the malarial infection also. We have already suggested that the monocyte does not act directly, but that the immunity response which effects a cure in malarial infection, though associated with a monocytosis, is of a humoral nature, and it is probably specific. Therefore, though a monocytosis is an essential factor in immunity response, specific stimulation is required before a specific immunity response to malarial infection will occur.

Acknowledgment

We are very much indebted to Dr. H. P. Choudhury for assistance with the statistical analysis of the tables that appear in this paper.

ON THE THERAPEUTIC VALUE OF THIO-SARMINE IN THE TREATMENT OF SYPHILIS

By A. DENHAM-WHITE, M.B., B.S., F.R.C.S.
LIEUTENANT-COLONEL, I.M.S.

Civil Surgeon, 24-Parganas, Bengal, and Superintendent, Voluntary Venereal Hospital, Calcutta

Late Physician, Medical College Hospital, Bengal
and

B. B. MAITY, L.M.F.
Calcutta

THE voluntary venereal hospital in Calcutta is the only government institution in India for the treatment exclusively of venereal diseases; only women are admitted here.

In this paper an attempt has been made to study the effect of thio-sarmine which is prepared in the Brahmachari Research Institute, Calcutta, for the treatment of syphilis.

The compound thio-sarmine is sulph-arsenobenzene or di-sodium-dioxy-diamino-arsenobenzene-methylene sulphonate, and is allied to sulfarsenol, kharsulphan, sulpharsphenamine, sulphostab, etc. It is a light yellowish powder readily soluble in water. The solution used is made with distilled water freshly boiled before use and cooled. The solution is injected immediately after preparation. We have used 10 to 20 per cent. solutions which are slowly injected either subcutaneously or intramuscularly into the deltoid or buttocks twice in a week.

Generally we begin the treatment with a dose of 0.3 gramme and gradually increase the dose up to 0.6 gramme and the average total amount of 5.1 grammes was administered to each patient. During the treatment the intermediate doses were repeated, if found desirable.

The toxicities of thio-sarmine, sulfarsenol, sulpharsphenamine are almost the same in experimental animals. Given intravenously the maximum tolerated dose of thio-sarmine = 300 milligrammes, majority tolerated dose = 360 milligrammes, and the minimum lethal dose

(Continued from previous column)

TABLE V
Some weeks after unsuccessful treatment; few parasites

Serial number	Number of monocytes in 50 fields	Number of histiocytes in 50 fields	Ratio M/H × 100	Probable error
52	5	19	26.33	
53	8	14	57.14

55	10	12	83.33	
56	6	18	33.33	
57	5	22	22.72	
58	4	19	21.05	
59	5	21	23.89	
Mean.	6	18.9	35.86	± 5.07

= 490 milligrammes, per kilogramme of body weight, in the case of white rats.

Cases which gave positive Wassermann reactions and showed syphilitic manifestations, either local or general or both, at the commencement of treatment were treated with the drug. The blood of each case was examined for Wassermann reaction before, and two to three months after completion of treatment.

The therapeutic value of the drug was proved by the disappearance of syphilitic manifestations and by the Wassermann reaction remaining negative after completion of treatment.

The total number of cases treated by thio-sarminine was 30; of these 23 gave a strongly-positive Wassermann reaction and 7 a moderately-positive reaction. They were all cases of secondary syphilis.

conditions markedly improved in all the cases. Reactions, such as diarrhoea, headache, gastritis, dermatitis were not observed in any of the cases during treatment. For effects on the Wassermann reaction see table I.

We made a comparative study of the value of thio-sarminine in the treatment of syphilis by using the following drugs:—

- I. Sulfarsenol.
- II. Sulfarsenol and bismostab.
- III. Novarsenobillon.
- IV. Novarsenobillon and bismostab.
- V. Novarsenobillon and mereurosol.
- VI. Stabilarsan.
- VII. Thio-bismol.
- VIII. Quino-ido-bismuth.
- IX. Bismuth-idol.

Results of treatment.—The ulcers when present healed up quickly, condylomatous and elephantoid conditions disappeared gradually, adenitis subsided in the majority of cases and in those which had no suppurative eruptions over the body disappeared, and the general

The symptoms of the cases treated by these drugs were more or less the same as in those treated with thio-sarminine and consisted of hard chancre, phagedenic sore, condylomata, elephantoid condition, adenitis, arthritis, secondary eruptions, cauliflower-like growths, gummatous

sore, iritis, keratitis, etc. A comparative statement of the effects of these drugs on the Wassermann reaction is given in tables II and III.

I. *Sulfarsenol*.—Total number of cases treated was 30; of these 19 gave a strongly-positive Wassermann reaction and 11 a moderately-positive reaction. Doses—12 centigrammes, 18 centigrammes and 24 centigrammes; two injections of each dose were given to each patient either intramuscularly or subcutaneously into the buttocks in 1½ months. In our experience, higher doses of sulfarsenol are not tolerated by the patients.

II. *Sulfarsenol and bismostab*.—Total number of cases treated was 10; of these 7 gave a strongly-positive Wassermann reaction and 3 a moderately-positive reaction. Doses of sulfarsenol—12 centigrammes, 18 centigrammes and 24 centigrammes; two injections of each dose were given intramuscularly or subcutaneously, and 6 injections of 0.5 cubic centimetre dose of bismostab were given intramuscularly to each patient alternately with the former in 2½ months. In our experience, higher doses of sulfarsenol and bismostab are not tolerated by the patients.

III. *Novarsenobillon*.—Total number of cases was 30; of these 27 gave a strongly-positive Wassermann reaction and 3 a moderately-positive reaction. Doses—0.3 gramme and 0.45 gramme; 4 injections of each dose were given intravenously to each patient in two months. In our experience, higher doses of novarsenobillon are not tolerated by the patients.

IV. *Novarsenobillon and bismostab*.—Total number of cases was 30; of these 28 gave a strongly-positive Wassermann reaction and 2 moderately-positive reaction. Doses of novarsenobillon—0.3 gramme and 0.45 gramme; 4 injections of each dose were given intravenously and 8 injections of 0.5 cubic centimetre dose of bismostab were given intramuscularly to each patient, alternately with the former in 2½ months. In our experience, higher doses of novarsenobillon and bismostab are not tolerated by the patients.

V. *Novarsenobillon and mercurisol*.—Total number of cases treated was 30; of these 27 gave a strongly-positive Wassermann reaction and 3 a moderately-positive reaction. Doses of novarsenobillon—0.3 gramme and 0.45 gramme; 4 injections of each dose were given intravenously and 8 injections of 1 cubic centimetre dose of mercurisol were given intramuscularly to each patient alternately with the former in 2½ months. In our experience, higher doses of novarsenobillon and mercurisol are not tolerated by the patients.

VI. *Stabilarsan*.—Total number of cases treated was 30; of these 27 gave a strongly-positive Wassermann reaction and 3 a moderately-positive reaction. Doses—0.3 gramme and 0.45 gramme; 3 injections of each dose were given to each patient intravenously in 1½ months. In our experience, higher doses of stabilarsan are not tolerated by the patients.

VII. *Thio-bismol*.—Total number of cases treated was 15; of these 13 gave a strongly-positive Wassermann reaction and 2 a moderately-positive reaction. Dose—10 injections of 0.2 gramme were given intramuscularly into the buttocks to each patient in 2 months. In our experience, higher doses of thio-bismol are not tolerated by the patients.

VIII. *Quino-ido-bismuth*.—Total number of cases treated was 15; of these 13 gave a strongly-positive Wassermann reaction and 2 a moderately-positive reaction. Dose—6 injections of 4 cubic centimetres were given intramuscularly to each patient in 1½ months. In our experience, higher doses of quino-ido-bismuth are not tolerated by the patients.

IX. *Bismuth-idol*.—Total number of cases treated was 10. Of these 9 gave a strongly-positive Wassermann reaction and 1 a moderately-positive reaction. Dose—8 injections of 2 cubic centimetres were given intramuscularly to each patient in 1½ months. In our experience, higher doses of bismuth-idol are not tolerated by the patients.

TABLE II

Showing the comparative value of thio-sarmine and other drugs in figures on Wassermann reaction after treatment in 240 cases of syphilis

	BEFORE TREATMENT			AFTER TREATMENT			
	Strongly positive	Moderately positive	Total number	Strongly positive	Moderately positive	Doubtful	Negative
Thio-sarmine ..	23	7	30	2	4	8	16

TABLE III

Showing the comparative value of thio-sarminc and other drugs, in percentage on the Wassermann reaction after treatment calculated from the figures in table II

	Strongly positive	Moderately positive	Doubtful	Negative
Thio-sarminc	6.6	13.3	26.6	53.3
Sulfarsenol	36.6	33.3	23.3	6.6
Sulfarsenol and bismostab ..	40.0	50.0	10.0	nil
Novarsenobillon	33.3	40.0	13.3	13.3
Novarsenobillon and bismostab ..	33.3	23.3	26.6	16.6
Novarsenobillon and mercuriosol ..	33.3	33.3	20.0	13.3
Stabilarsan	56.6	23.3	16.6	3.3
Thio-bismol	53.3	26.6	13.3	6.6
Quino-ido-bismuth	40.0	40.0	13.3	6.6
Bismuth-idol	40.0	30.0	nil	30.0

Observations

(1) It will be seen from the above that thio-sarminc is a most efficacious drug in the treatment of syphilis and its manifestations.

(2) Intolerance towards this drug is much less than with other arsenobenzene compounds.

(3) The effect on the Wassermann reaction is remarkable in the case of thio-sarminc as will be seen from tables II and III; the largest number of cases showing negative Wassermann reaction after treatment was noted in the case of thio-sarminc.

In compiling this paper we have not in any way selected cases for treatment as being likely to respond, but each case has been taken in the order of admission, irrespective of the gravity of disease or nature of symptoms. All cases have been positive in blood reaction and without exception the lesions have been gross and extensive. Side by side with thio-sarminc treatment, other cases have been undergoing treatment with other preparations. Amongst the advantages we have noted clinically are absence of reaction in cases treated with thio-sarminc. The temperature hardly ever rises, and there is practically no pain. There have been no nitritoid crises, nor anaphylactic conditions and hitherto no arsenical dermatitis. The drug may be regarded as one of the most innocuous at present in use, its lack of toxicity being most marked in comparison with its high efficacy. It appears to be, so far, most suitable both for hospital and private use. Furthermore the rapidity with which symptoms disappear compares very favourably with other preparations. Our experience in this hospital is that the ordinary Indian female patient is intolerant of novarsenobillon in doses over 0.45 gramme and it is our practice never to exceed this. The usual onset of dermatitis when it occurs is after the 4th injection, or if the dose of 0.45 gramme has been exceeded. With thio-sarminc the maximum dose has been up to 0.6 gramme without the slightest effect. It is to be remembered that the dosage of the arsenical compounds, such as novarsenobillon, neosalvarsan,

etc., has been based on the physical characteristics of the European and it is now known that the Indian female cannot tolerate a dose well-borne by her European sister. This does not, however, seem to apply in the case of thio-sarminc. We have observed no case in which the Indian female has shown intolerance even in the higher doses. It therefore appears clinically that it is of a comparatively low toxicity.

THE ANTIGENIC POWER OF ANTI-DYSENTERIC BILIVACCINE, AS DEMONSTRATED BY A SEROLOGICAL METHOD

By PROF. P. SEGUIN

Institut Pasteur, Paris

SINCE the work of Besredka has popularised the methods of oral vaccination, different methods have been sought of effecting by means of oral administration, vaccination against cholera, typhoid, paratyphoid and bacillary dysentery. Numerous controlled attempts in the course of important epidemics have led us to affirm the great preventative value of oral vaccines and especially bilivaccines prepared according to the methods of Besredka.

However, as the serum of subjects immunised by the oral method contains only exceptionally and in the smallest degree specific antibodies, it was natural that a method should be sought of checking the antigenic value of oral vaccines. It is to this task that Wats and White (1931) have recently applied themselves.

These writers, after injecting into a rabbit emulsions made from tablets of antidysenteric vaccine, have never been able to obtain in the serum of the prepared animals specific agglutinins, and they have come to the conclusion that it is impossible to find dysenteric antigen in tablets of oral vaccines.

I have repeated the experiments of Wats and White and have arrived at opposite conclusions. While giving repeated injections of concentrated emulsions of antidysenteric bilivaccine into the veins of rabbits, I have observed in the

course of a few weeks the appearance in the serum of prepared animals of a relatively high titre of antibodies agglutinating the different strains of *B. dysenteriae*. As my conclusions are obviously opposed to those of the above writers, I feel I ought to give in detail one of my experiments.

I used tablets of antidysenteric bilivaccine bearing the serial number 273; these had been prepared a year and a half ago. Each tablet contains about 80 milliards of bacilli.

B. shiga 40 milliards.

B. flexner 20 milliards.

B. strong 10 milliards.

B. hiss 10 milliards.

Three tablets (that is to say a full dose) were crushed in 10 c.cm. of physiological saline and carefully emulsified. I thus obtained an emulsion of which I injected 1 c.cm. into the vein of rabbit 69 B. Eight days afterwards I prepared in the same way a new emulsion of which I injected 2 c.cm. The following week I injected 3 c.cm. of a new emulsion. Finally, a fourth injection was made of 4 c.cm. of an emulsion which was again freshly prepared.

The rabbit had therefore received intravenously in the space of 4 weeks 10 c.cm. of emulsion corresponding to the quantity of microbes contained in three tablets of antidysenteric bilivaccine. These experiments are summarised in the following table :—

	Date	Intravenous dose	REMARKS
Rabbit 69 B 2.45 kilo- grammes.	26-11-31	1 c.cm.	The animal in good health and giving no trouble.
	3-12-31	2 c.cm.	
	9-12-31	3 c.cm.	
	16-12-31	4 c.cm.	

The animal was bled 8 days after the last injection and its serum was tested against emulsions of different strains of *B. dysenteriae*.

The emulsions intended for the experiments were made directly from cultures grown for 24 hours on gelatine.

The emulsions of bacteria were used at a titre of about 60 million per c.cm.

These experiments were carried out by the macroscopic method. The tubes for the experiment were subjected to a temperature of 37°C. for 1½ hours and were then left for half an hour at laboratory temperature. We will now proceed

to the reading of the results. These are summarised in the following table :—

Dilutions

Strains used	1/100	1/200	1/300	1/500	1/1,000
Shiga.					
French, XX	+++	+++	+++	+	—
Indian, 84	+++	+++	+++	+	—
Indian, 247	+++	+++	+++	+	—
French, 162	++	++	++	—	—
Flexner.					
No. 33.	+++	+++	+++	+	—
Indian, 45	+++	+++	++	—	—
Strong, 12	++	+	—	—	—
Hiss, 3	—	—	—	—	—

It is clear from the reading of this table that all the strains which have been made use of, except the *B. dysenteriae* of Hiss, have agglutinated in the presence of the serum of the prepared rabbit.

Shiga and Flexner strains have strongly agglutinated in a dilution of 1/300.

Note that the strains of *B. shiga* 247 and 162 and the Flexner strain have not been utilised for the preparation of tablets of *B. dysenteriae*, the emulsions of which have been injected in the rabbit.

To conclude, there is no doubt that although the degree of agglutination observed is neither as high nor as easily obtained as that which is readily observed in the case of animals injected with heated microbial emulsions freshly prepared from a strain of *B. dysenteriae*, it is nevertheless possible to make specific antibodies appear in the serum of the rabbit by using as an antigen tablets of dried microbes. It is sufficient to inject strong doses and to make an adequate number of injections.

I attribute the absence of anti-Hiss agglutinating bodies in the serum of the prepared rabbit to the fact that this microbe is the one which in the composition of the tablet is represented by the weakest dose of dried microbes.

I think I have proved that it is possible, by making use of the prescribed technique, to give evidence of the antigenic value of antidysenteric bilivaccine by the method of specific agglutination.

A Mirror of Hospital Practice

A CASE OF LYMPHOCYTIC LEUKÆMIA*

By FREDRICK H. REYNOLDS, M.B., Ch.B. (Edin.)

Civil Surgeon, Loimwe, S. Shan States

K. B., A GURKHA, aged 45 years, was admitted into hospital on 23rd June, suffering from a mild attack of irregular fever. His complexion was sallow and he was

emaciated. He had had malaria on and off, and had been taking quinine and alkalies as an out-patient, but showed no improvement. His spleen and liver on admission were just palpable, his blood did not show any malarial parasites, and there were no signs of leukæmia at this stage. He did not improve, so I examined him again on third day and found that his spleen and liver were enormously enlarged. The spleen extended 5 inches below the costal margin in the mid-axillary line and 8½ inches below it in the mammary line; the

* Rearranged by the Editor.

liver was four inches below the costal margin. The blood picture was as follows:—

Total red corpuscles per cubic centimetre ..	3,200,000
Hæmoglobin ..	55 per cent.
Total white corpuscles per cubic centimetre ..	50,000
Small lymphocytes ..	90 per cent.
Large lymphocytes ..	5 "
Polymorphonuclear cells ..	2 "
Eosinophiles ..	3 "

There were a few polymorphocytes, mast cells and nucleated red cells, also poikilocytosis and granular degeneration.

The patient perspired a great deal throughout. His abdominal and thoracic veins were distended and prominent, and here and there was marked pigmentation, but no actual hæmorrhagic areas. There was no retinal, nasal or other hæmorrhage. On admission he had slight œdema of his legs and ankles, which soon passed away.

The patient suffered a great deal from dyspnoea towards the end; this cannot all be accounted for by the enlarged spleen. His cervical, axillary, and inguinal glands were enlarged on both sides of his body. They were uniform in size, but the enlargement was slight, and they were not adherent to each other or to the skin. He was treated with arsenic and adrenalin, but the treatment was of no avail, and the patient died on the eighth day after admission and 16 days after the onset of the disease.

Comments.—This case is of interest because of its sudden onset, and its very short duration. Acute lymphocytic leukaemia is usually a disease of children and young adults but this patient was 45 years old.

The blood picture showed a preponderance of the small lymphocytes which constituted 90 per cent. of the whole white cell count. The man had not suffered previously from syphilis or tuberculosis, nor was there any history of trauma, though the constant attacks of malaria may have been a predisposing cause. A post-mortem examination was not permitted and therefore further pathological findings cannot be recorded.

A CASE OF PURPURA HÆMORRHAGICA

By S. L. BHANDARI, P.C.M.S.

Assistant Surgeon in-charge Civil Hospital, Sheikhpura

On 11th April, 1932, B. D., a married girl, aged 16, was brought to the hospital from a neighbouring village with alarming symptoms of bleeding from the throat, nose, and under the skin.

Previous history.—Bleeding from throat for four days; headache 24 hours previously, hæmorrhagic spots on legs, arms and abdomen, in the mouth, and under the conjunctivæ for the last 24 hours; and bleeding from the nose for the last 24 hours.

Condition on admission.—Temperature, 101°F.; pulse, slow and feeble; anæmic and debilitated; profuse bleeding from nose and throat; hæmorrhagic spots from pin points to the size of a large pea, on legs, arms, chest, and abdomen, as well as inside mouth, on tongue, and under the conjunctiva of the right eye; but no bleeding with urine, stools, or expectoration.

Progress of the case and treatment.—

11th April.—Calcium lactate in 20 grains doses was given by mouth every 4 hours. Bleeding was less up to 12 midnight, but started again.

12th April.—8 A.M. Bleeding still considerable; clotted blood in mouth and nose; hæmorrhagic spots

had increased both in size and number. Two cubic centimetres of hæmostatic serum was given intramuscularly at once, along with 20 grains of calcium chloride in 10 cubic centimetres of water intravenously, and the following mixture was prescribed, to be taken every four hours:—

R. Olei terebinthæ rectificati minims xv.
Acidi sulphurici aromatici .. minims xxx.
Aquam chloroformi ad .. 1 ounce.

10 A.M.—Bleeding was less.

12 noon.—Bleeding was still considerable; pulse, imperceptible; pallor had increased.

Six cubic centimetres of hæmostatic serum was given intramuscularly.

5 P.M.—Bleeding stopped; pulse just returning and perceptible with difficulty.

10 P.M.—Patient asleep; pulse better.

13th April.—No more bleeding; pulse much better; hæmorrhagic spots subsiding.

The remaining days were uneventful and the patient was discharged cured on 20th April.

AN ARROW WOUND OF THE ABDOMEN

By D. N. GUPTA

Medical Officer, In-charge Sadar Hospital, Ranchi

D. M., an aborigine of Chota Nagpur, was admitted into the Sadar Hospital, Ranchi, on the evening of 25th February, 1932, with a wound in his abdomen made by an arrow which was still *in situ*. He had been hit in the morning at about 9 A.M. of the same day. The illustration shows the position of the arrow. An operation was performed and the arrow was removed; it was found to have pierced the abdominal wall and the parietal peritoneum, and to have damaged the great omentum. Recovery was uneventful and the patient was discharged cured on 11th March.

The bow and arrow is still in vogue amongst the aborigines in this part of India. From a medico-legal point of view it is important to note that these people commonly use aconite on the tip of the arrow for homicidal purposes and for big game hunting. In this case there was no such poison used.

ENCEPHALITIS LETHARGICA IN ASSAM*

By NISANATH GHOSH, M.B.
Teacher of Medicine, Berry-White Medical School,
Dibrugarh, Assam

Occurrence in Assam.—So far as the knowledge of the writer goes no case report of encephalitis lethargica has yet been published from Assam. Hence he ventures to record his observations.

In 1926 the writer happened to see in a village in the Surma Valley a comparatively young man with symptoms of paralysis agitans. This made him suspect the prevalence of encephalitis lethargica in sporadic form in Assam.

Since 1926 several suspicious cases and at least 3 undoubted cases of encephalitis lethargica have come to the notice of the writer.

Fig. 1.

Case 1.—B. C. D., Hindu, male, aged 25 years, a cultivator by occupation, was admitted in the Dibrugarh Hospital on 21st September, 1929.

Past history.—He had coryza and fever about a month prior to admission. The fever lasted for about two weeks. He was unconscious during that period. After that there was a change in his temperament. He became violent and abusive and used to spit here and there. For the last 10 days before admission he was becoming dull and listless.

Condition on admission.—He was dull, and apathetic. His face was expressionless and he lay motionless in

*Rearranged by the Editor.

bed for hours on end with his eyes closed. The patient used to pass urine and faeces into the bed and did not take food unless fed with a spoon.

Examination.—His eyes showed—ptosis, slight lateral nystagmus, unequal pupils and sluggish pupillary response to light. No sign of facial or palatal paralysis was discovered. In erect posture his body was slightly bent forwards with the arms in front kept semiflexed and rigid. All movements were slow and stiff. Athetoid movements and tremor of the fingers, tremor of the tongue and eyelids were found. Speech was indistinct. He was very slow to respond to calls and never gave intelligent answers to questions. He could not walk and when he attempted to do so there was a tendency to fall forwards. The attitude and facies were suggestive of Parkinsonism. Knee-jerks were exaggerated. Babinski's sign was markedly positive. The feet were slightly cedematous. The pulse rate was 75 per minute and the temperature, was 98.4°F. There was no well-marked rigidity at the neck. Kernig's sign was absent. Urine, normal. Lumbar puncture yielded clear fluid under normal pressure, with a few lymphocytes. The general appearance of the patient is seen in the accompanying illustration which was taken after about two weeks' stay in the hospital.

Treatment.—Besides occasional symptomatic remedies hexamine was used regularly. Hyoscine hydrobromide was used for the Parkinsonism and lessened the rigidity appreciably. He was taken away from the hospital after about a month's treatment on 24th October, with the lethargy and rigidity somewhat improved.

Fig. 2.

Case 2.—The patient, named S., Hindu, female, a coal-mine coolie aged 30 years, was admitted on 23rd January, 1931, and was discharged on 16th February, 1931.

Her complaints were.—Inability to move about properly and inability to work for the past five months, after an attack of fever lasting for one week during which she remained unconscious for three to four days.

Past history, habits, etc.—She came to Assam in her babyhood and has never been outside the province since

then. She is accustomed to smoke tobacco, to take tea and occasionally alcohol. She has had occasional attacks of fever, each of short duration, in the last two years—the last attack ending in the present trouble.

Condition on admission.—Her attitude, facies and gait were typically Parkinsonian in character. Rigidity of the body and limbs was very marked. Tremor was present but was not exactly of the 'pill-rolling' type and it used to disappear on sleep. All movements were sluggish and stiff. Speech was slow and indistinct. Knee-jerks were very brisk. Babinski's sign was doubtful. The right eye had a squint. The eyelids were tremulous on closure and the tongue was tremulous on protrusion. The patient was apyretic and could manage to move about unaided. The spleen was enlarged 3 inches below the costal arch. Accompanying illustrations of the patient in two positions show many of the above-mentioned features.

Fig. 2a.

Treatment.—Hyoscine and hexamine were mainly used. Very little improvement was noticed on discharge.

Case 3.—The patient, named B., Hindu, male, aged 24 years, was admitted on 24th March, 1932, and on 1st April, 1932, he was removed by his relatives from the hospital, against medical advice.

Complaints.—Inability to walk about and extreme listlessness and idiotic behaviour for the past fortnight.

Past history, illness, etc.—He was said to be literate enough to sign his name in English prior to his illness. About three weeks before admission he had fever lasting for one week. After the fever the present symptoms were noticed.

Condition on admission and during stay in hospital.—His attitude and facies were suggestive of Parkinsonism. He was unable to walk unaided, so his gait could not be tested. On standing up he had a tendency to fall towards the right side. There was ataxia and slight drooping of the right upper eyelid and also squint in the same eye. He was dull and listless but sometimes kept wide awake all night. He lost his speech and made an ineffectual attempt to write, resulting in

scribbling only. Urine and faeces were usually passed into the bed. Knee-jerks were normal. Babinski's sign was absent. There was slight rise of temperature at times. Lumbar puncture was not done.

Treatment.—The same as in case 2. Though the patient stayed for a short time in the hospital there were definite signs of improvement at the time of discharge. He was more wakeful than before, was able

Fig. 3.

to stand up unaided and his squint had disappeared (see accompanying illustration). All these improvements were probably due to a natural process and not to the treatment he had in these few days.

The writer is grateful to Lieut.-Col. Colin McIver, M.D., D.T.M. & H., I.M.S., Superintendent, B. W. Medical School for his encouragement and valuable help.

LEECH BITE OF LABIUM MAJUS*

By C. S. P. HAMILTON, M.R.C.S., L.R.C.P.

Juri Valley Medical Association, Kapnapahar Tea Estate, Juri, South Sylhet

THE following case is of interest in that the symptoms might have led to a diagnosis of uterine hæmorrhage being made.

I was called to see a lady who was suffering from hæmorrhage.

* Rearranged by the Editor.

Her last period was two weeks previous to this hæmorrhage, and as far as she could say was perfectly normal. She awakened on the morning in question feeling very fit; however, she became alarmed on seeing a patch of recent blood in the bed, and naturally thought she had uterine hæmorrhage. She did not complain of any local pain, and funnily enough not even of local irritation (which is generally marked in leech bites).

The patient sent for me as the hæmorrhage became more severe, but just before my arrival she got out of bed and trod on 'something slimy', which proved to be a large leech.

On examination a leech-bite wound, which was bleeding freely, was found on the right labium majus.

No other source of hæmorrhage was discovered, and there was no further bleeding.

LEPROSY RELIEF IN INDIA

A REVIEW OF THE PRESENT SITUATION, AND A SUGGESTED POLICY FOR PROVINCIAL AND LOCAL AUTHORITIES.

By E. MUIR, M.D., F.R.C.S. (Edin.)

and

J. LOWE, M.D., Ch.D.

School of Tropical Medicine, Calcutta

The gravity of the problem

THE 1921 census gives 102,513 as the number of lepers in India, but mentions that this is short of the real number, as only conspicuous sufferers from this disease were likely to be enumerated by the untrained people who gathered the statistics. Recently, an estimate was made by the sanitation staff of a certain town in India that there were only six lepers in a certain ward of the town. Immediately after, a second survey made by skilled workers showed that there were at least 144 lepers (24 times the original figure) in that ward, and in all probability even more. It is not suggested that the 1921 census figure should be multiplied by 24 in order to arrive at the number of lepers, but we are safe in calculating that there are from one half to one million lepers in India.

Leprosy is not a very fatal disease. Compared with malaria, tuberculosis and cholera there are comparatively few deaths. But after all the death roll is not the only criterion of the suffering caused by a malady. Leprosy probably accounts for more mental, if not physical, suffering than any other disease in the country. To many lepers the prospect of speedy death instead of long years of suffering would come as a welcome relief.

While in some parts of India leprosy is decreasing, there seems to be no doubt that in other parts improved communications by rail and road, and the opening up of highly endemic areas hitherto isolated from their surroundings, are leading to marked increase and dissemination of the disease.

Recent surveys have brought to light the important part which industrial concerns play in the spreading of leprosy infection. The workers in industrial areas are drawn from different parts of the country and from different classes. The various human elements discard their customary class rules to a large extent when they leave home; they tend to mix

promiscuously, often in insanitary or crowded surroundings; and thus we have ideal conditions for the spread of a chronic infection like leprosy. This state of affairs has been brought out by our survey figures which show an incidence of at least one per cent. in almost all industrial areas, and this number rises to three per cent., or even higher, in some places. A very heavy responsibility devolves upon those who are in charge of sanitary measures in these areas.

B. E. L. R. A. (Indian Council) and its policy

The Viceroy appealed in 1924 for funds to form a branch of the British Empire Leprosy Relief Association in India. A sum of over 20 lakhs of rupees was subscribed and the question arose as to the best method of using this money. Since the discovery of the bacillus of leprosy by Hansen in 1872, the accepted method of dealing with the disease has been through segregation in leper asylums. Judging from the expense involved in founding and running these institutions it would not have been possible to arrange for the segregation of more than one or two thousand lepers with the amount available. Moreover the majority of lepers who migrate to such institutions have in the past been those who have reached the last stage of the disease in which the infection is dying out, and who have already spread the infection to their relations and neighbours.

New line of campaign.—It was decided therefore that a new line of campaign was necessary. Research had recently shown two things:—(1) that leprosy can be diagnosed with ease in almost every case at a stage when the patient has not begun to be infectious and a danger to others, and (2) that at this stage most cases treated efficiently and for a long enough time recover.

It is easily understood therefore that a scheme which aims at diagnosing and treating all early cases and organising prevention is likely to be much more effective in controlling leprosy than one which can only hope to segregate in asylums some two or three thousand out of the half to one million lepers of India.

Accordingly the policy adopted by the Indian Council of the British Empire Leprosy Relief Association has been:—(1) the diagnosis and treatment of all but especially early cases, and

(2) prevention. In order to secure this, the following programme is being followed out :—

1. *Training of doctors.*—Till recently leprosy has not been considered a remediable disease. It has therefore not been studied by the medical profession, and many doctors are unable to diagnose any but the most obvious cases. If early cases are to be diagnosed and effective treatment is to be adopted, it is necessary for all doctors to become acquainted with the disease especially in its early stages and to know how to treat it. Instruction in leprosy is now given to the students of many medical schools. Short courses of instruction have also been held in Calcutta, four every year and each lasting two weeks, at which doctors from the various provinces and states of India have received the necessary training. Many of those who have attended these courses have trained other doctors in their own provinces, and in this way, as well as by means of suitable literature, it is hoped that within a few years most of the doctors in India will be as conversant with leprosy as they are with malaria.

2. *Survey of incidence of leprosy.*—Obviously, if effective means are to be taken to deal with leprosy, we must know in what parts of India the disease is most common and among what classes of the community it is most rife. Also, if a higher incidence is found in certain areas and among certain classes of people, the reason for this must be ascertained. The census taken in the first year of each decade enumerates only the more obvious cases and, as has been mentioned above, the real incidence is probably from 5 to 10 times as great.

Obviously, it is impossible to make an accurate survey of all India. It has been found that a party of five skilled workers take one month to survey a thana with a population of 40,000 people. It would therefore take 70 such parties, working for 10 years, to survey all India. What was done was to appoint a party, which visited the various provinces and states in turn, making demonstration surveys in an area of each province which had been ascertained by the 1921 census to be highly leprosy. The effect of this sample survey was to induce provinces and states to appoint similar survey parties of their own to carry on work along similar lines.

The method of carrying out a survey is as follows :—

A treatment centre is started in what has been shown to be a highly endemic area. Infectious cases are followed up to their villages and contacts are examined for early signs of the disease. The villagers are shown by practical demonstration, posters and magic lantern slides what are the early signs of leprosy, how the disease is conveyed from one person to another and also that good results can be had from treatment. In this way the good-will and confidence of the people are won, and patients, instead of trying to hide their disease,

come forward in the hope of being cured. It is possible to carry out a much more thorough census by the propaganda-treatment-survey method than could be done otherwise.

3. *Propaganda.*—After all, the most important factor in stamping out leprosy is isolation of infectious cases, and this can only be done as the result of propaganda and gradually educating the community as to where the real danger lies. The Association has prepared and distributes literature both for doctors and for the lay public. Among the latter an illustrated booklet entitled 'What the Public should know about Leprosy' has been translated into eleven Indian vernaculars, and sets of lantern slides, along with an explanatory booklet, can be obtained. A series of five leaflets has been prepared for distribution and has been translated into several vernaculars. *Leprosy in India*, a journal which acts as a record of progress of anti-leprosy work in India, with notes on methods used in other countries, is published quarterly.

4. *Research.*—Although the last activity of the Association to be mentioned is research, it is not the least item, but the most important of all. It was as the result of research that the Association was begun, and it is on its findings that the above programme has been founded. Much has still to be found out, for leprosy is a difficult disease to understand. Unlike the sister disease, tuberculosis, it is doubtful if its causal germ has yet been grown outside the human body; and the mode of infection and spread in the body, though worked out to a certain extent, still remain mysterious. Then much has yet to be done to improve the treatment of leprosy, and this can only be done through careful practical study by experts.

Provincial branches.—Most of the provinces and some of the states have branches of their own and a certain proportion of the funds of B. E. L. R. A. is set apart to be distributed to these branches. As examples of the work being done in various provinces by the co-operation of the provincial branches of the B. E. L. R. A. and the local governments, we may quote the following :—

Bengal.—Here the leprosy work of the province is organised by the Bengal branch of the B. E. L. R. A. with the aid of grants from government, municipal authorities, local boards, etc. There is a leprosy propaganda officer for Bengal who has visited nearly all the districts, organising courses of instruction for doctors, carrying on propaganda work, and as occasion arises doing brief surveys and starting clinics.

In addition there is a survey party of one chief and three assistant doctors who have thoroughly surveyed some of the areas of Bengal in which leprosy is most common, doing propaganda work and establishing clinics, which after the survey are then carried on by local doctors under district authorities and industrial concerns.

An interesting feature of the Bengal work has been the survey of industrial areas, jute mills, mines and tea gardens.

In Bengal there are over seventy leprosy clinics started by the B. E. L. R. A. workers and being carried on by doctors appointed and supported by local authorities.

The Bengal branch has a small income which has been sufficient to support only one good leprosy officer; but he, by ability and keenness, has been able to enlist the co-operation and financial support of government and local authorities, so that the work has developed widely. If the funds of the B. E. L. R. A. had been used to finance clinics, the result would have been only two or three clinics and not the present large number.

Madras.—The survey party of the Indian Council of the B. E. L. R. A. has visited this presidency on two occasions and as a result the Madras Government, in consultation with the senior writer, have drawn up a scheme of anti-leprosy work in the presidency. The presidency has been divided into six areas for each of which has been appointed a special leprosy officer to carry on propaganda and survey work, create treatment centres attached to suitable medical institutions, train doctors, and generally organise and co-ordinate leprosy work. By co-operation with the public health department it is hoped to complete a more or less accurate register of all leprosy cases detected. This it is planned to check by quinquennial surveys by public health authorities.

Attempts have been made in Madras to co-ordinate the work of leper asylums and leprosy clinics.

There are in existence about 80 clinics financed by government and local authorities. The funds of the Madras branch of the B. E. L. R. A. are handed over to the government to help to pay for the leprosy staff.

Madras being more developed than many other parts of India the government are able to consider the organisation of a definite scheme of widespread leprosy work. The progress of this work will be watched with interest.

Bihar and Orissa.—This branch distributes part of its income in grants to clinics and hospitals treating leprosy. The government had a leprosy officer and a survey party, and it was reported in 1931 that there were 36 clinics. In addition there was a whole-time leprosy officer in the Puri district, and an annual grant from the Bettiah Raj estate paid for two whole-time leprosy officers in the Champaran district.

The government have as a measure of economy abolished the post of leprosy expert and the survey party, so that in spite of a considerable amount of money being available from the B. E. L. R. A. and other sources, the development of anti-leprosy work in Bihar and Orissa is likely to be handicapped.

Central Provinces.—After a visit of the B. E. L. R. A. (Indian Council) survey party in 1928,

a leprosy specialist was appointed and a survey party of four doctors was formed. Systematic survey work was carried on and 32 centres were established. Sixteen of these were placed under the charge of special assistant medical officers working under the public health department, the remainder being run by local dispensary doctors. The special assistant medical officers run leprosy treatment centres and subcentres; they carry on steady propaganda and survey work in villages and combine with their leprosy work a considerable amount of general public health and epidemic work. This work has steadily progressed. The clinics run by the local assistant medical officers in connection with the existing dispensaries and hospitals have not been nearly so successful, and experience has shown that leprosy work is best done in the Central Provinces under the public health department by special officers who make leprosy work one of the main activities in a campaign for rural public health.

The work in the Central Provinces is an interesting experiment in the use of methods of organisation rather different from those used elsewhere. Every year survey work is done and an increase in the number of clinics and patients is recorded and the results are reported as being very encouraging.

Reports of work done in other provinces are published in the annual report of the B. E. L. R. A. (Indian Council).

The results of this work

(1) *Survey work.*—The survey has brought out many useful and interesting facts among the chief of which are these:—

- (a) Leprosy is most prevalent among semi-aboriginal tribes who have left their aboriginal seclusion but have not yet adopted the modern sanitary measures common among more civilised people.
- (b) Leprosy frequently enters better class families through these semi-aboriginals when they are employed by such families as servants.
- (c) A single highly-infectious case may often infect not only a village, but indirectly a group of villages.
- (d) The commonest form of leprosy found is the 'neural' form showing anæsthetic macules or acroteric lesions. These cases are presumably non-infectious since no bacilli can usually be found in them. Some of these cases undoubtedly progress later to the cutaneous form which is infectious, but some of them do not. Some cases, exactly what proportion it is difficult to say, undergo spontaneous arrest. At any one time two or three 'neural' cases are found to each 'cutaneous' case.

- (e) The finding of large numbers of slight cases in a village indicates one or two

things. Either the disease has been newly introduced and is spreading rapidly; or the village has long been infected but, since the people have a high degree of resistance, the disease takes a mild form.

- (f) There is generally a fairly obvious predisposing cause. Often there is some other disease, such as syphilis, malaria, hookworm disease, or filariasis. Sometimes it is the diet of the people. At other times it is the climate or geological conditions resulting in occasional famine or chronic under-feeding. These causes vary in various districts, in different villages, and in individuals.

(2) *Treatment and prevention.*—One of the results of this campaign is the general recognition that the leprosy problem, though a difficult one, is not incapable of solution. Large numbers of special leprosy clinics have been started, and in many general dispensaries provision is now made for the separate treatment of leprosy on certain days. A recent questionnaire sent round at the request of the League of Nations shows that at the end of the last year there were 59 residential institutions for leprosy in India with a total of 9,634 inmates, most of whom are under treatment; also that there were 213 out-patient clinics, either special or general, in which leprosy was treated. All this shows that it is now generally recognised that leprosy treatment is worth while. But unfortunately the great majority of patients lack perseverance, or are unwilling to take the time and trouble required for complete recovery. Also ignorance, superstition, unhealthy surroundings, and adverse economic conditions stand in the way of their improvement.

It is however being realised more and more that treatment alone is never likely to stamp out leprosy in India. Efforts to get patients to attend regularly for treatment must not be diminished, but the chief function of a leprosy clinic should be prevention. It is easier to prevent a dozen cases of leprosy than to cure one.

Prevention can only be carried out by following up the patient from the dispensary and visiting him in his own home. As far as possible every clinic should make arrangements for this follow-up of patients, and specially trained workers may be necessary to do it efficiently. General propaganda, such as may be given in the clinic itself, is not likely to carry much weight. Leprosy is primarily a village disease, and it is not the single person but the community that forms the village unit. The whole village must be instructed and persuaded, otherwise there will be no permanent result. Moreover the outlook and interests of villagers are narrow; they are not interested in abstract ideas and general statements. It is necessary for the leprosy worker to visit the

village, follow up the infectious case, gain the confidence of the inhabitants and enquire into the history of the origin and spread of the disease in that particular village. From this information he should prepare his special propaganda, explaining not in general but in particular terms how leprosy can be prevented.

Leprosy can only be controlled by limiting the opportunity of spreading infection. We do not know the exact mode of spread of leprosy, but certain important facts are now generally accepted. Leprosy is spread by contact of infective cases with healthy people. The more intimate the contact and the greater the period of contact, the greater is the danger. Children and young people are much more susceptible to leprosy than adults. Prevention must aim at preventing this contact specially with young children. Isolation of all infective lepers in institutions is impracticable in India, but much might be done to carry out isolation in villages and in homes. The type of contact which is most dangerous is the type which is commonly seen in joint-family houses at night, infective lepers sleeping together with healthy members of the family in a small crowded room. This should if possible be prevented. In some villages it may be possible to have huts put up outside the village where infective lepers should live and sleep. They can go about and work if possible during the day, but they must sleep in separate quarters at night. The same applies to the homes of lepers. A separate room or a hut outside the joint-family house, for the infectious case to live and sleep in, is very essential. Even now this is sometimes provided by the families of lepers, but only when the patient has become deformed, unsightly and ulcerated. This is too late. Many patients have been infective for years before they reach this state, and in fact the deformities and ulcerations are often a sign that the infective stage is drawing to a close. The village or home isolation must be carried out much earlier and much more efficiently. Too often one sees infective lepers living in a separate hut, but attended by the children of the family. Thus the home isolation is rendered worse than useless, for children are much more susceptible to leprosy than adults. In home and village isolation, arrangements must be made for separate eating and drinking utensils, as well as for separate sleeping accommodation, and the importance of protecting children from infection must be realised.

The great predisposing causes of leprosy in India are the bad social and hygienic conditions of the people. Bad housing, bad diet and debilitating diseases render people susceptible to leprosy and provide the conditions under which leprosy spreads. Therefore all measures which tend to improve social and hygienic conditions and to help people to love a healthy life will also tend to bring about a diminution in leprosy. Leprosy propaganda should therefore merge into the wider sphere of general public health work.

The following figures are extracted from the official report for 1930. The figures for that year are chosen for quotation as it is for that year that they are published in a form which lends itself to this analysis. In that year too, the Health Boards Enactment had placed all estates, European and Asiatic, under the charge of a medical officer.

drainage of this sort, with neither oiling nor any other auxiliary has been found in this practice sufficient to control *A. ludlowi*.

Anopheles umbrosus has been dealt with entirely by concentrating all water, and maintaining it open to the sunlight in clean-cut channels or containers free from all surface vegetation. The application of oil has

TABLE I
Hospital and death rates for 1930

		Population	Hospital admissions	Hospital rate per mille	Deaths	Death rate per mille

* Comprising: 387 benign tertian, 131 sub-tertian, 17 quartan, 29 undefined, and 33 carriers without symptoms.

The problem of malaria in Malaya has been noteworthy for its high epidemicity especially when the work of agricultural expansion was taking place. As the country grew so did the serious aspect of malarial sickness and death. All methods of control by clinical treatment seemed of equal success inasmuch as they had no effect for the better. At this juncture, when the whole commercial foundation of the country was at stake, the advent of anti-larval methods took place.

The area to be dealt with being widespread agricultural country, what has become known as species sanitation was adopted, so that the anti-larval attack was directed only against those mosquitoes which were the proven vectors in the district. These anti-larval measures varied therefore with the species found and their natural predilections for certain environments and conditions, and with the topography of the locality.

The malaria vectors implicated were *Anopheles ludlowi*, *Anopheles umbrosus* and *Anopheles maculatus*. While admitting the possibility of other species being upon occasion capable of carrying infection, the writer's experience is that, in Malaya, in the absence of these three species, epidemic malaria does not occur.

The earlier work in this practice has been described elsewhere (Watson, 1921), and the methods there given in detail have been followed with but little alteration since that time. In the writer's experience success still invariably follows the proper application of anti-larval methods for the control of malaria, but, except in so far as a record of success of any particular method is of itself evidence in its favour, these notes are not intended as a defence of any one method as opposed to another. They are simply a record of experience of the writer in the field of malaria control.

Anopheles ludlowi, the brackish water breeder is dealt with by bunding and the provision of good drainage through tide gates. This mosquito is, of course, typically found on the coast, but with faulty and leaking bunds and gates, or in their absence, it is surprising how far inland it may be found on flat land. Efficient

proved, not only unnecessary, but ineffective in controlling this species.

Measures against *Anopheles maculatus* have also depended primarily upon drainage, that is, on the concentration of all water in well-defined channels. These have been either of sub-soil type, or open concrete channelling or open earth drains. Only the last have been oiled.

Drainage, it will be noted, is the basis and *sine qua non* of all the anti-larval methods employed, and the progress of these measures towards some degree of perfection the writer hopes to show below.

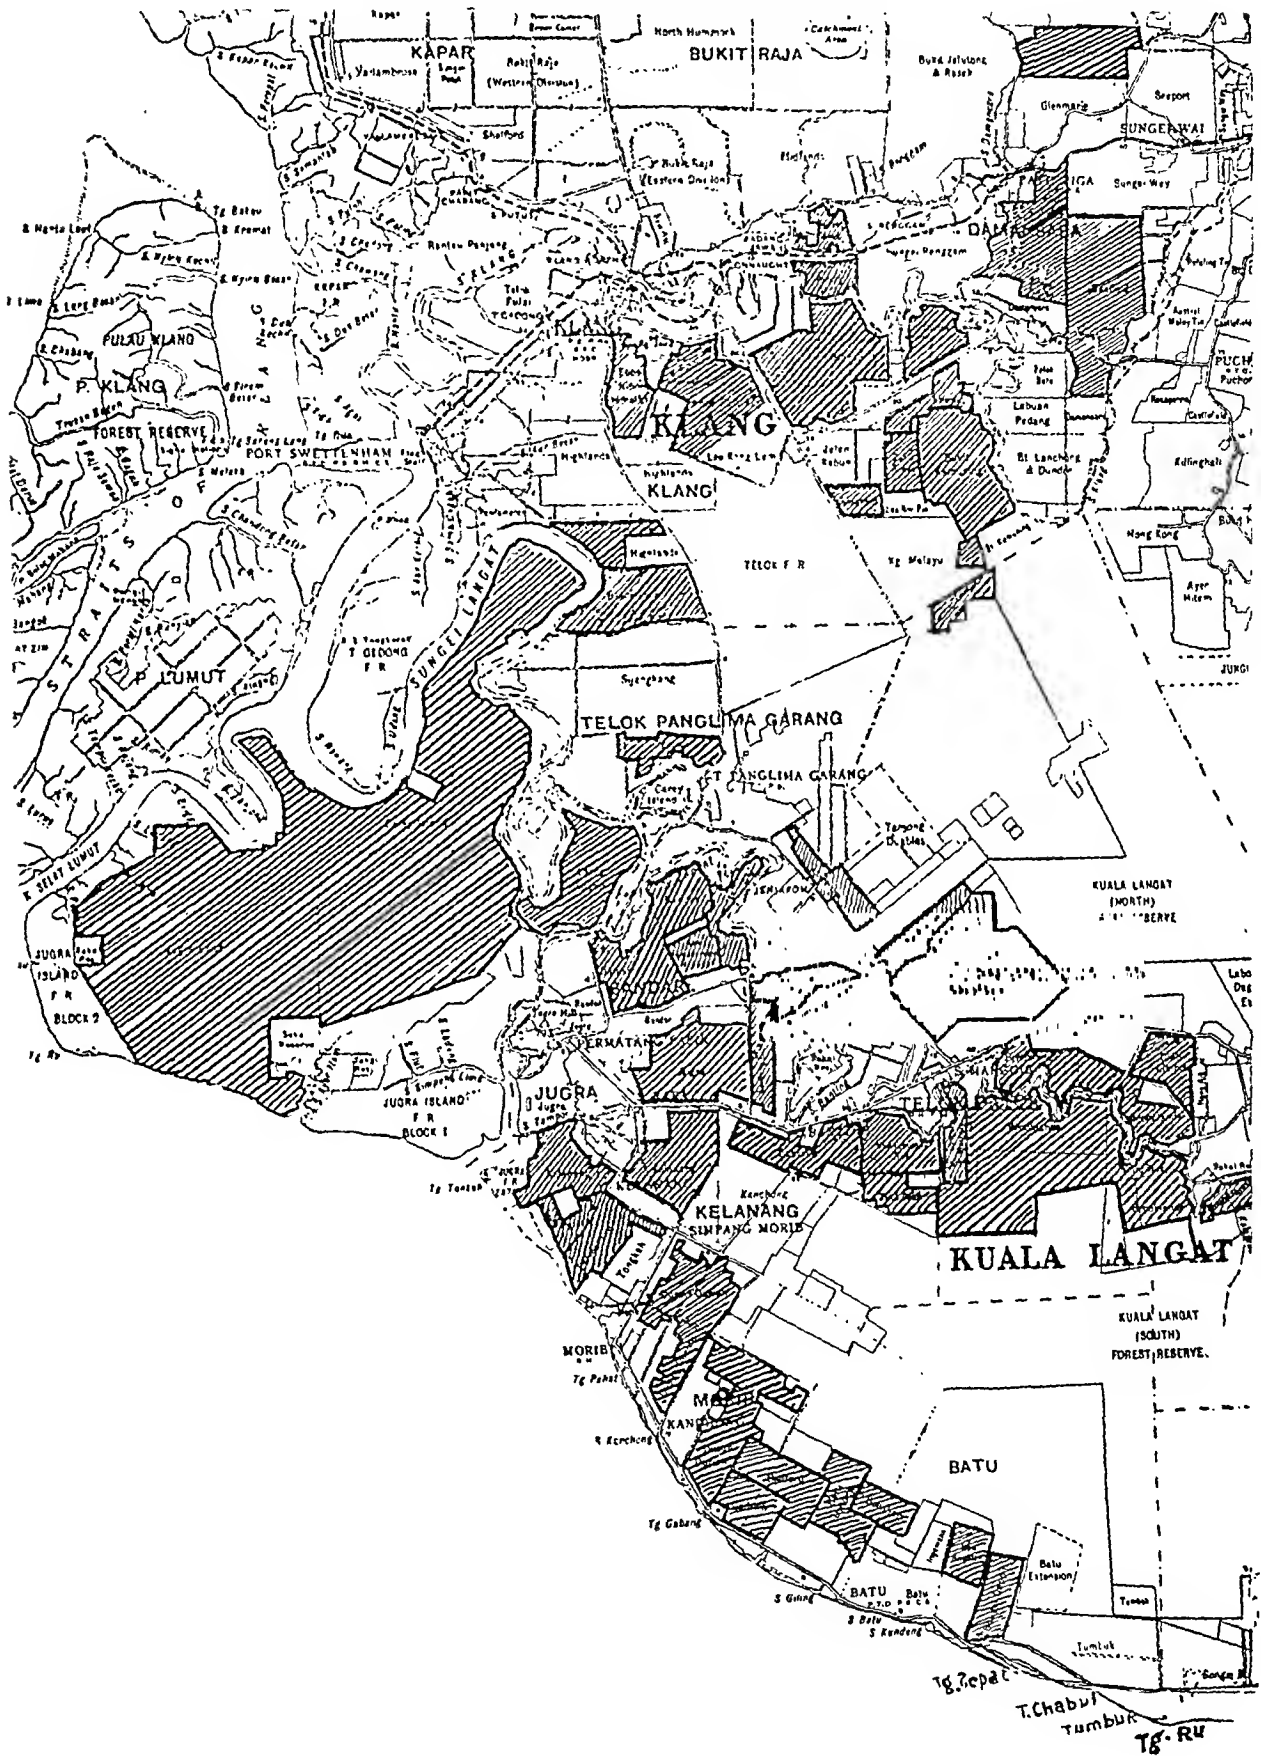

Scientifically, anti-larval methods seem logical and sound in principle. It may be claimed, however, by critics that no controls are available. It is admitted that controls for each little peculiarity are difficult to obtain, but in some cases there are such controls which are considered good enough for the purpose. Moreover, controls due to the removal of anti-larval methods and the re-introduction of these methods in the same locality are available.

The whole subject of anti-larval control in this country has been tried and tested *pari passu* with the progress of knowledge of the subject, until a stage has been reached which, if not of perfection, is at least one of a high degree of success. It is the writer's opinion that, if these methods were pushed to the limit, no economic factor intervening, practical perfection would obtain. To support this contention examples will be given on separate entities and of the factors which counteract actual perfection being obtained. The latter factors will be explained and enumerated first so that a better criticism of the estate results can be made. These factors fall chiefly under the following heads—(i) topography, (ii) the human element, (iii) insufficiency of quarantine or of control over the population (estate immigration and visiting), and (iv) the economic factor.

The topographical factor is probably the most insistent counteracting influence. This is best appreciated by a study of the map of the locality. Here we see anti-larval control on small estates more often than not

MAP I

Map of the district. The estates of this practice are shaded and show the large periphery liable to invasion by mosquitoes and malaria.

hedged round by other agricultural land which has no mosquito control in any form. These alien areas are often within mosquito striking distance of the habitations of the controlled labour forces, although to avoid this should be the first step of an anti-malarial policy. This is made apparent when no long view has been taken and temporising measures have prevailed. With foresight and courage most of the heavy initial expenditures on attacks on Nature's strongholds would actually have paid in a short time, but where, for example, the control area round the habitations is insufficient, on account of unwillingness to face initial expenditure, a definite counteracting factor to perfect anti-larval control is present.

Even when more than half mile from housing, these areas still form a source of infection to night visitors. Furthermore, work on an estate often starts in the half light of the morning and workers may be infected while operating near these boundaries. With most estates there is a relatively large boundary line thus adjacent to a non-controlled and endemic area.

The human element in all ventures is apt to fail at times and no less so in any method of malaria control. The carrying out of the various procedures must be definite and exact, and here alone error may occur. Constant care must be as permanent as the structures used, and work put off till to-morrow will surely exact its toll. As the effects of good anti-malarial work can only be seen in a negative light there is a great temptation at times for a worker to allow himself a certain amount of easing up. This negative character of the evidence of the best work in malaria control often, too, tempts the onlooker to consider as the most superfluous, the worker with the greater achievement to his credit.

The total number of cases of malaria treated on Carey Island during the past five years has been 159, or 0.6 per cent. per annum of a population of five thousand persons.

Of these 52 were admitted within 10 days of arrival on the estate, 27 were admitted between 10 and 20 days, 23 were admitted between 20 and 30 days.

Of the remaining cases 17 gave a history of fever elsewhere during the previous six months and 9 during the previous one year. Of the remaining 31 cases 14 had the infection traced to the uncontrolled Sakai reserves on the island. Only 17 cases or 0.6 per cent. per annum remain unaccounted for. These include all parasite carriers who had shown no clinical symptoms, but whose blood had been examined as a routine measure.

If, in order to satisfy the most critical, we accept as imported only those cases detected within ten days of arrival, we have one-third of the cases imported. As communication with Carey Island is by private ferry and costs money, it is clear that this proportion must be very much higher on healthy estates completely surrounded by easily-accessible infected country.

The anti-malarial measures adopted on Carey Island consist of deep drainage and well-constructed and well-supervised tide gates, and the siting of all housing over half a mile from uncontrolled areas. The potential vectors are *A. ludlowi*, and, to a lesser extent, *A. umbrosus*. No oiling has been done on Carey Island, which has over 17,000 acres under cultivation, and the malaria incidence since 1921 has been under one per cent. per annum.

This work on Carey Island was conducted from the opening up of the estate, and has prevented the introduction of epidemic malaria to any important extent to the foreign labour brought to work the estate.

TABLE II
Malaria rates on Carey Island estate

Year	Population	Malaria cases	† Malaria rate per mille	Malaria deaths	* Malaria death rate per mille
1921	4,400	60	13	4	0.9
1922	4,321	26	6	2	0.4
1923	4,424	20	4	1	0.2
1924	4,573	16	3	1	0.2
1925	4,844	15	3	nil	nil
1926	5,223	24	4	1	0.2
1927	5,651	28	5	nil	nil
1928	5,197	36	7	1	0.2
1929	5,838	38	7	2	0.3
1930	5,410	32	6	1	0.2
1931	4,989	25	5	nil	nil

* All cases having parasites in the blood are included, whatever the specific cause of death.

† Includes imported cases. No correction for these cases is made in any of the tables given.

There have been times in the history of every estate when labourers were required in increasing numbers. This immigration, especially in times of exigency, had no effective control. Here a leakage took place and there appeared in the labour force cases of malaria whose infection had been contracted on the unhealthy estates from which they came. No control over the population has ever been effective as regards their habits of wandering from one area to another, whether for one night or for extended periods of time.

The map of the area of this practice clearly indicates the vast opportunities provided for these imported cases, much of it being small detached areas completely surrounded by uncontrolled country where anopheline vectors, high spleen and malaria rates, of anything from 30 per cent. to 100 per cent., abound.

As an example of the extent to which such imported cases can effect the incidence rate in areas under full control the figures of Carey Island estate, where some form of quarantine is possible, are of value.

Several controls are available for the work done. Carey Island is identical in character to, and is situated at the mouth of the same river as, Port Swettenham, and the malaria history of that port is well known to have been so bad that, after it was built, the Government ordered it to be abandoned.

Two areas of uncontrolled Sakai (aboriginal) reserves on the island itself, with their numerous *A. ludlowi* and *A. umbrosus*, and their high malaria endemicity, are further controls for the work on the cultivated portion of the island.

There have too been incidents in the history of the estate which themselves serve as controls. Some years ago 300 coolies left the island and went to an estate in Malacca. Some months later 200 returned, all heavily infected with malaria. No isolation of these reservoirs was attempted yet no infection was passed from them to any other cooly.

A contrast to this was provided in 1920, when 19 cases of malaria occurred in one division. This outbreak was

traced to a disused well which had been allowed to become overgrown with weeds and in which *A. umbrosus* was found. In 1928 five cases of malaria occurred in coolies who had not left their division. A survey revealed a few *A. ludlowi* in the drain. Further investigation showed a slight undermining of the tide gate controlling the area, which permitted the ingress of salt water.

Over the area of the practice where malaria was already hyper-endemic among the labour forces before work was started the figures of past years are incomplete in some respects, but with every person known to have had malaria more than once in the year, progress is fairly shown by the annual death rates. In the past all statistics were noted for workers only and the death rates of these, from all causes, fell from 67 per mille in 1908 to 8.5 per mille in 1930.

surveys using thick blood films, the technique followed being that described by Green (1931).

These have been as yet completed only for a relatively small area. In the case of the estate which produces the highest malaria rate, viz, 10.0 per cent. per annum, the parasite rate was 11.3 per cent. When a sufficient length of time for proper observation has elapsed the results of treatment with plasmoquine on these carriers will be reported.

Estate P. in 1930 gave an incidence rate of malaria of 5.3 per cent. of the population per annum. A parasite survey, by the officers of the Institute for Medical Research, of 415 persons gave 32 positive or 7.7 per cent. The hospital books of this estate show that at one time a 'burial gang' drew, almost constantly, overtime pay for their work, and the death rate was for years around

CHART I

Death rates from all causes of estate workers

As the incidence of malaria fell below 100 per cent. this has been recorded separately for the whole population, and over an area of some 130 square miles, of what was at one time as malarious a part as anywhere

300 per mille per annum. The malaria incidence rate in 1931 was 1.2 per cent.

Chart II shows the malaria incidence and death rates for the entire area of this practice since 1921, while the

CHART II

Rates per mille over the whole practice

Population = 17,000 \pm 4,000.

in the world, the malaria incidence for 1931 was 2.4 per cent.

Now that an incidence rate has been obtained which is no greater than that which might well be caused entirely by imported cases, attention is being directed to the parasite rate as obtained by complete blood

three following charts show these rates for the *ludlowi*, *umbrosus* and *maculatus* areas, respectively. Since these areas overlap they have been divided so that the area described as *umbrosus* is composed of those estates where no other vector is found. Where *A. umbrosus* is found in addition to either of the other vectors the estate

is included in the *ludlowi* or *maculatus* area as the case may be. It is this duplication of species with opposed preferences as to breeding conditions which makes this area so much more difficult to control than those parts where only one vector has to be considered.

In these charts are included in each year all estates, whether under our control throughout the year or only for part of the year.

In the matter of effectiveness and of costs even the old subsoil drainage on this estate more than proved its worth over the fourteen years it remained, as reported by the writer (1932).

In 1926, however, the old piping was replaced. The year 1925 had been a dry one and the roots of the nearby trees had sought out the water in the pipes, which they had partially choked in some places, although this

1930	96	1.7
1931	73	2.8

In combating *A. maculatus* two main methods are employed, viz, oiling and subsoil drainage. Shade and other methods are on no estate solely depended upon although they play their part.

Chart VI shows the malaria incidence on estate S. F. which has been subsoil-drained against *A. maculatus*. The pioneer work on this estate is described in full by Watson (1921, chapter XII), but the system as it exists to-day has been considerably modified as a result of the experience gained since that time, both on this estate and elsewhere.

did not become apparent until the excessive rainfall of 1926 when the narrowed pipes were unable to cope with the great amount of water during the floods of that year. Water seeped to the surface and was unfortunately oiled. The result of this oiling was that after the choked pipes had been repaired the oily silt prevented the water reaching, not only the newly-laid pipes but also the unbroken lines. It was therefore decided to relay the entire system. In relaying them the pipes were laid deeper and they are now five feet deep at least, and are laid in loops along the hillfoots

to discharge into open drains on the flatter part of the ravines. These drains are 22 feet wide at top and 2 feet at bottom which is laid with concrete channeling.

more evident that a malariologist is not merely a physician or an entomologist or a civil engineer, but something of all three.

CHART VI

Rate per mille on subsoil-drained area

Population = 800 \pm 250.

* Note change in scale of graph.

The earth sides of the drains are laid with turf and they have stood up excellently to the tremendous scour, even on Seafield estate. Only at their termination have they required repair and there the heavy

Chart VII shows the figures for these estates where oiling was considered the method of choice. The only method now used of applying the oil is by spraying from a knapsack sprayer by cooly labour.

CHART VII

Rate per mille on oiled area

Population = 2,200 \pm 300.

concrete inverts have been carried 40 to 50 feet by the scour.

Pipes are still upon occasion choked by roots. No difficulty is experienced in keeping pace with the repairs as oil is now never used over a seepage. Paris green, 5 per cent. in smoke-house dust, spread by hand, has proved satisfactory for this purpose. One ravine has been left under the old system and is being used for certain observations.

The writer's experience of subsoil drainage on estates by some other workers leads him to emphasise that such drainage is not intended to carry off storm water. The ravines must therefore be levelled and graded so as to allow free passage to the open drains of surface water. The application of oil too over subsoil pipes will ruin the piping and only by complete removal of the oily soil and replacement by fresh can this be remedied. As emphasised elsewhere, in this work as in other spheres, multiple control can never be so effective as competent single executive. It is becoming more and

During these years new estates have from time to time been added to the area of the practice. This has tended to cause periodical rises in the incidence rates over the whole. Chart VIII represents the malarial incidence on these estates which first came under our control in 1922, from that year to 1931.

In 1928 the writer noted a comparative ineffectiveness in the anti-malarial oil mixtures which had previously given satisfactory results. These mixtures were being compounded from the same prescription as before, that is, Diesel fuel oil, solar oil and kerosine in certain proportions. These oils remained the same as regards their burning properties but investigation showed a difference in certain other properties. At a meeting of the Malaria Advisory Board to the F. M. S. Government, the writer (1931) drew the attention of the Board to his experiments on the subject of these mixtures, and Corbett and Hodgkin (1931) confirmed, almost entirely, these experiments under full laboratory conditions. These workers minimized the importance of

volatility, but further stressed the importance of surface tension and viscosity.

The writer has conducted further experiments in the field and, although much work is yet to be done before any final conclusions can be justified, the following figures even suggest a range within which these qualities of the oils should fall for successful anti-mosquito spraying in Malaya.

drained areas. Estate K. (chart IX) has been drained with a view to proper oiling, while estate S. N. (chart X) has been oiled as efficiently as possible over simple agricultural drainage. Both estates have a history of malaria rates in the past of around 100 per cent. per month.

The necessity for constant technical supervision of oiling is well demonstrated in the case of estate H.

CHART VIII

Rates per mille on newly-controlled estates

Population = 500 \pm 150.

Year	Cases	Malaria incidence rate per mille per annum*
1922	3,716	5,133
1923	508	1,229
1924	38	111
1925	16	41
1926	20	38
1927	14	22
1928	20	35
1929	8	14

1931	6	14

* Note change in scale of graph.

The Asiatic Petroleum Company generously supplied samples of their various oils and very kindly undertook the analysis of a number of mixtures of these oils, some of which had been found successful and some unsuccessful for larval control.

The results of the analyses showed that:—

(1) Although the *flash point* of all successful oils fell within the limits of $81^{\circ} \pm 10^{\circ} \text{C.}$, many unsuccessful oils were also within this range.

(2) The *specific gravity* too showed little relationship to the success, although all successful oils fell within the range 0.870 ± 0.02 .

(3) All successful oils had a *viscosity* (Enggler at 30°C.) of 1.4 ± 0.3 . Some unsuccessful samples of the lighter oils also came within this range.

On this estate the manager elected on his own responsibility to alter the oiling to some practice of his own.

The average malaria incidence rate per month for the previous two years had been 0.3 per cent. After one month from the initiation of the ineffective oiling this incidence was 3.5 per cent. per month, which was again reduced to 0.1 per cent. per month over the succeeding years by proper oiling.

It is always noticeable that the results following such an outbreak are better than those immediately previous. In other words after a manager has been personally convinced of the necessity of the persistent care in the maintenance of the work, his part of it is done much more thoroughly than when it is done merely because his board tells him to do so.

CHART IX Estate B. K.

Month	Malaria rate per cent.	Month	Malaria rate per cent.
January	nil	January	0.4
February	nil	February	0.2
March	nil	March	1.2
April	0.2	April	1.8
May	nil	May	3.5
June	0.8	June	2.8
July	nil	July	0.8
August	nil	August	1.0
September	nil	September	0.8
October	nil	October	nil
November	nil	November	0.5
December	0.2	December	0.9

(4) All successful oils had an *average volatility* within the range $283^{\circ} \pm 7^{\circ} \text{C.}$ The unsuccessful oils were all either less than 234 or greater than 325.

(5) All successful oils had a *surface tension* of 32.6 ± 1.1 dynes per cm. No unsuccessful oil came within this range. All unsuccessful oil mixtures tested were greater than 34.2.

It has been said that oiling should be considered as supplementary to drainage as an anti-malarial measure. Proper results cannot be obtained by oiling unless all water to be oiled has been defined, and the two estates, topographically as nearly comparable as possible, whose monthly figures over one year are shown below (charts IX and X) demonstrate the difference which is to be expected between suitably drained and unsuitably

CHART X Estate S. N.

March	1.2
April	1.8
May	3.5
June	2.8
July	0.8
August	1.0
September	0.8
October	nil
November	0.5
December	0.9

Much the same experience has been had in *umbrosus* country. Some years ago a fairly large area dissociated itself from my practice and, arguing that malaria having been absent for many years, the careful maintenance of the anti-larval drainage was no longer imperative, elected to abandon anti-larval drainage and to maintain only agricultural drainage. As malaria reappeared large quantities of oil were used for spraying without however affecting the increase of malaria.

For four years this policy continued, after which time the area reverted to my control and proper anti-larval methods suitable for the conditions of the area were reinstituted.

During these years the annual incidence of malaria rose from 0.9 per cent. per annum to 31.2 per cent.,

only to fall again to 0.6 per cent. when proper measures were reinstituted (chart XI).

Another recrudescence of malaria in *umbrosus* country occurred in my consultant practice. The estate T. M. had apparently been free from malaria for some thirteen years and had a sharp outbreak in October of one year. Within a month the management gave the malaria incidence as 100 per cent. and at the time of my own

extension of the control to the full half mile but this was done only to the quarter-mile limit. This proved successful although *A. ludlowi* continued to breed at this radius and for some miles beyond. No other vector was implicated in this epidemic.

The measures against *A. umbrosus* elsewhere also remain unchanged, viz, the concentration of all water in sunlit or flowing channels kept free from all surface

CHART XI

Proper anti-larval control was abandoned from the middle of 1925 to the middle of 1929. visit in April of the next year every cooly had malaria. All Europeans had had fever and so many visitors to the estate had been infected that it was being deliberately avoided. The spleen rate, which had been recorded as nil for many years, was 73 per cent.

This case is of interest in more respects than one. The incriminating vector had been considered to be *A. ludlowi* and there is little doubt that this mosquito was associated with the beginning of the epidemic, but on my visit *A. umbrosus* was found breeding in the drains, which in the past had been kept clean-weeded but which for motives of economy were then uncleared. Some *ludlowi* had been found breeding at 16 chains from the lines and these places had been heavily oiled without however effecting the malaria. At my visit however, they were found breeding at 35 chains from the cooly lines. As this area of breeding had been in existence during the years when there was no malaria I advised reversion to the anti-larval methods against the *A. umbrosus* only. Such control also removed the *A. ludlowi* breeding spots at 16 chains.

This work was commenced in May. Since August of that year, 1931, to date, October 1932, no case of malaria has occurred.

vegetation. Small epidemics have occurred (e.g., five cases among a labour force of 174 on estate C.) as a result of a long drought providing breeding places for *A. umbrosus*. The drains and wells on the estate were kept scrupulously clean on their sides, but some vegetation existed on the bottom. With water some feet deep in the drains this was of no importance, but as the drought continued the drain became merely a series of small pools shaded by this growth. *A. umbrosus* was found breeding in these pools within 40 yards of the rooms used by the five cases of malaria; one of these patients possessed a vegetable garden at the jungle edge half a mile distant, and he is presumed to have imported the parasite.

Other recrudescences of malaria from this vector have occurred. On estate B. the management closed an outlet drain to the north of the estate in the month of November. A new outlet was provided farther south, but the smaller drains were not regarded and were left to silt up. Water therefore lay in them and soon became shaded by grass. *A. umbrosus* reappeared in them and, as the estate is frequently visited by outsiders, reservoirs were readily available. The malaria incidence is shown in chart XII. The outlet was reopened in the

CHART XII

Malaria incidence rate per mille on estate 'B'

An interesting point is that *A. ludlowi* are still breeding in their usual profusion at a 35 chain radius and for some miles beyond. In view of the suggestion of a longer range of flight of this mosquito this is of interest and fails to support the theory. There is ample fresh water around the lines and adjoining their brackish breeding places.

I recall another case which fails to support this suggestion regarding the flight range of *A. ludlowi*. An epidemic of malaria had occurred in a township which had extended its boundary to within a few hundred yards of the uncontrolled area in which were *A. ludlowi* in their customary abundance. I had advised the

month of June and *A. umbrosus* disappeared along with the malaria.

These results have all depended upon anti-larval methods of control, but the writer does not wish to appear to deprecate the use of chemo-prophylaxis in its proper place. The judicious combination of both clinical and anti-larval methods will no doubt take us further with more ease than either alone, but it is surely the chemo-prophylactic measures which must be supplementary to established anti-larval methods and not *vice versa*.

While of opinion that chemo-prophylaxis may keep the death rate of a small population within reasonable

bounds, or even control the malarial incidence in a small and isolated community, the writer cannot believe that it can ever be successfully applicable to labour forces generally in this country with populations around one thousand and with the constant changes which occur in their individual units.

The writer has made use of chemo-prophylaxis upon occasion and in at least one case has had apparent absolute success in the control of malaria with plasmoquine and quinine. The circumstances of that estate were however exceptional.

In 1928 an experiment was started with drug prophylaxis on an estate which, however, it was impossible to complete.

The estate is situated on the edge of *maculatus* land and extends into *umbrosus* country. Anti-larval control on the flat land had been maintained for many years but *A. maculatus* had never been found on the estate till 1927. This is explained by the fact that the adjoining land on the hilly side of the estate had been controlled and *A. maculatus* had never jumped this barrage to settle on the small area of hillfoot seepage on the estate. In June 1927 however it was first found there. No measures were taken, by intent, and it was not until February 1928 that malaria appeared in epidemic form. This took place one month after a considerable number of the coolies had visited a festival at a neighbouring estate. For 19 months mass treatment with quinine was tried with no success (see footnote).^{*} It had been intended to continue this treatment for two years, this being about the time after which a tentative conclusion of the effectiveness of chemo-prophylaxis can be justified, and then to use plasmoquine. The management however refused to allow further experiment and anti-larval methods had to be instituted. The figures in chart XIII show that during the years 1924 to 1927 the average monthly malaria rate was 0.3 per cent. During the years 1928 and 1929 when quinine was given it was 2.5 per cent. Since anti-larval measures (oiling) have been used the rate as was to be expected has been 0.02 per cent.

In the case referred to above where plasmoquine and quinine appeared to give good results, the locus of the experiment was a small estate being opened up out of a block virgin jungle situated on the foothills and surrounded by impenetrable forest and swamp. No position for housing was possible which would allow of even a quarter mile radius for anti-larval control and *A. umbrosus* was breeding in unusually large numbers. *A. maculatus* had also been found. Adult *A. umbrosus* can still always be found in the temporary hutments erected for the population of 140 persons.

Since its inception the estate has been one hundred per cent. malarious. Visitors even for one night invariably returned infected. Severe cerebral and blackwater cases were frequent. As new planting had to be undertaken new coolies were employed and every one became infected.

Mass distribution of quinine had been undertaken, but in spite of it the spleen rate was 82 per cent. and the stream of severe cases to hospital continued, so that only one-third of the labour was available for work at any given time.

In January 1931 it was decided to try mass administration of plasmoquine. The estate is in the district under the direct charge of the senior assistant, Dr. Lawrence A. Watson to whom, during the writer's leave, all details of the experiment were left.

Owing to the extreme isolation of the estate, personal supervision could not be undertaken and it was decided

to distribute the drug in small doses combined with quinine in capsule. To reduce liability of error administration was effected at each of two musters in the day, on the principle of 'no capsule—no pay'.

The dose of plasmoquine was small but the treatment was continued for 21 days, the dosage being: quinine bihydrochloride, gr. $7\frac{1}{2}$ with plasmoquine gr. $\frac{1}{15}$ (0.004 gm.) twice daily. This treatment was first given in February, 1931. Neither during nor after this treatment has there been any case of clinical malaria whatever.

After three months the 21-day programme of the same doses was repeated. Another three months later a 14-day course of quinine bihydrochloride gr. $7\frac{1}{2}$ with plasmoquine gm. 0.005 twice daily was given. This programme was repeated again in three months time, and again in February, May and August 1932.

Not a single case of clinical malaria has occurred during the twenty months following the first treatment in February, 1931, although in September, 1931, a parasite survey, using thin blood films showed 26 per cent. to harbour parasites.

In August 1932 an examination was made of thick blood films from every coolie resident on the estate. These now numbered only 48. Of these 48 persons 2 only, or 4.16 per cent., showed parasites. Both were subtertian infections although they had had no fever.

At varying periods during the experiment coolies were transferred to a healthy estate where they were kept under observation. In all, the after history of 42 persons was thus recorded:—Of these, 39.5 per cent. were found to harbour parasites on their transfer and were given a 14-day course of quinine gr. $7\frac{1}{2}$ with plasmoquine gm. 0.01 twice daily. There remained still infected 18 per cent. and these were given another similar course. Unfortunately all of them left the estate before further observation could be made.

Among the 42 persons thus transferred from the experimental estate there were 4 double infections of *P. vivax* and *P. falciparum*. After one course of treatment the *P. vivax* in one and the *P. falciparum* in another had cleared up. The other two were free from both.

The small population and its extreme isolation together with its diminishing numbers is felt to have contributed an essential factor to the success of this experiment. It is intended shortly to double the population on the estate and Dr. Watson will report the whole experiment together with the results of this immigration at a later date. As soon as the population is again stabilised the high dosage of quinine will be reduced and an attempt made to assess the relative value of the quinine and the plasmoquine.

^{*} In administering quinine the writer selects a dose equal to $1\frac{1}{2}$ grains per stone of body weight per diem. For mass treatment an arbitrary adult daily dose of 10 grains was usually selected for a Tamil labour force, and this given to every worker and dependent on the estate. The dose was adjusted for children and infants were given euquinine in condensed milk.

IMMUNITY IN PROTOZOAL INFECTIONS

BACTERIAL immunity is a subject which has been the centre of intensive study for at least fifty years, consequently a considerable amount of knowledge has accumulated, and, even if this has not been crystallized to the satisfaction of the precise-minded, at least teachers of this subject are in a position to summarize the present-day theories of bacterial immunity without introducing any acutely controversial matter. The same cannot, however, be said of protozoal immunity. Medical protozoology is a much younger science and in some ways a less important one. It is true that the one specific micro-organism which can claim annually the largest number of victims throughout the world is a protozoan, but on the whole the scope of the protozoa for causing disease and death is much more limited than that of the bacteria. The immunological aspect has been considered *pari passu* with the growth of our general knowledge in protozoal diseases and each worker on a special organism or group of organisms has considered the immunity question as applied to his own particular subject, but immunity in protozoal diseases in general has only been taken up as a serious study in comparatively recent years. Many able workers are now involved in this study, but we must give Professor W. Taliaferro the credit of being a pioneer.

There are two schools of thought—or perhaps one should describe them rather as tendencies in the minds of different workers—in this subject. There is the view that protozoa—like bacteria—are parasites, that the body defence mechanism is unlikely to differentiate between micro-organisms of different kingdoms but will exert the full force of its defence mechanism against any invaders, that therefore the immunity response against protozoal infection will be the same as that against bacterial infection, and that we have only to apply the knowledge gained in the one subject to the other. There is the opposing view that, protozoal parasites being animals within animals, there is no immunity response in the ordinary sense of the word, that their death is due to their failure to obtain suitable food or is only incidental following the phagocytosis of the blood cell in which they lie, and that the lytic processes of the body are only active against dead protozoa. The truth, as ever, lies somewhere between these two extreme views.

We have suggested above that the study of immunity against protozoal infection is a young branch of the science of immunology; it enjoys

the advantages and suffers the disadvantages that are always the lot of a younger generation. Workers on protozoal immunity have the general principles of immunity—mostly based on studies in bacterial immunity—already laid down for them, but it often falls to them to demonstrate to other workers, who have accepted the dictates of analogy too readily, that many of these general principles do not apply in the case of protozoa—and to disprove an accepted theory is notoriously more difficult than to establish a fresh hypothesis.

One of the main disadvantages under which the protozoologist, in contradistinction to the bacteriologist, works is that the blood-inhabiting protozoa—and it is with these that practically all work on protozoal immunity has been done—cannot be cultivated so readily outside the human body and that therefore much of his experimental work has to be done *in vivo*. Yet again this is possibly a blessing in disguise and he is on much safer ground when he draws an analogy between the behaviour of a parasite in an animal and that of a similar parasite in man, than when he has to compare the behaviour of the same parasite in man and in a test-tube.

On the other hand protozoa possess certain distinct advantages over bacteria for purposes of immunological study. Those with which we work mainly are larger organisms and therefore they are more easily enumerated, cell division can be observed and the rate of multiplication estimated, and the processes of their phagocytosis and destruction can be more easily followed. Furthermore, there are many protozoal infections which are not fatal to their hosts though the parasites may appear in enormous numbers in their blood; a very good example of such a parasite is *Trypanosoma lewisi* in the rat. It has been shown that in the serum of a rat infected with *T. lewisi* two distinct immune substances develop; the first checks reproduction of the trypanosome and the second has a trypanocidal action. The reproduction-inhibiting antibody is passively transferable and will stop reproduction in the trypanosome in a second rat before this rat's own reproduction-inhibiting antibody has had time to develop. This antibody is not absorbed by the trypanosomes *in vitro* and when washed trypanosomes whose reproduction has been inhibited are transferred to a new uninfected host they will commence reproduction at the ordinary rate. The trypanocidal antibody is also passively transferable, and when injected into a second rat in the early stages of an infection will cut short the infection, but when once the second rat's own trypanocidal antibody has developed no further reduction in trypanosomes can be brought about by the injection of trypanocidal serum from another rat. This suggests that, as in the case of pathogenic trypanosomes, those which resist the trypanocidal action become resistant to subsequent action by this same agency, whether it be drug or antibody.

The trypanocidal antibody, unlike the reproduction-inhibiting antibody, is absorbed by the trypanosomes *in vitro*, and trypanosomes, that have been thus subjected to the action of the trypanocidal antibody, are sensitized, so that when they are injected into a normal rat they are immediately destroyed.

These observations, which were made by counting and measuring the trypanosomes at frequent intervals in a way that would not have been possible had it been a bacterial infection that was being investigated, suggest a fairly complicated antibody mechanism, comparable to that in many bacterial infections; furthermore, the evidence points to this immunity response being mainly of a humoral nature, though admittedly it is claimed by some workers that the final disposal of the trypanosomes is by non-specific phagocytosis.

The plasmodial infections furnish another example of protozoal parasites which lend themselves to investigation by numerical methods. Human malaria is not a good example as the parasites are subject to tissue localization, so that the peripheral blood does not provide a fair sample, as regards parasitic population, of the blood throughout the body; it is for example well known that the segmented forms of *Plasmodium falciparum* do not appear in the peripheral blood at all. Certain avian plasmodia, however, are very suitable for study as they are not subject to tissue localization. A good example is *P. cathemerium* in the canary; here the immunity mechanism is very different from that of *T. lewisi* infection in the rat. There is no reproduction-inhibiting antibody and reproduction follows its regular 24-hour cycle at all stages of the infection. There is, however, evidence of a plasmodicidal immunity mechanism. It has been shown that the rate of multiplication of the parasites represents a 5-fold increase every 24 hours. Now the mature schizont divides into about 15 merozoites so that there is a daily loss of 10 merozoites, which can only in part be accounted for by the side-tracking of some parasites into the sexual stage. This loss is constant, and must be looked upon as evidence of a *natural immunity* in the bird. This 5-fold multiplication of the parasites does not go on indefinitely, and end in the parasitization of the whole erythron and the death of the bird, but after a certain time the process is checked, not by a slowing down of the reproduction cycle, which still goes on as before, but, by elimination of the parasites. There is at a certain stage a sudden very marked fall in the number of parasites, which means that whereas before the loss was represented by 10 out of 15 parasites going astray each day, the survival rate is now represented by one merozoite in, say, 10 rosettes, which means a loss of 149 out of every 150 parasites each 24 hours. It is by no means certain that the casualties all occur amongst merozoites—in fact we have histological proof to the con-

trary; cells of the reticulo-endothelial system are seen containing all forms of malarial parasites in different stages of digestion. Whatever is the change that brings about this state of affairs it must be looked upon as an *acquired immunity*. It is maintained by the host for a long period of time during which super-infection with the same parasite is not possible. There is evidence to show that this acquired immunity, which occurs in all plasmodial infections, is a species-specific if not a strain-specific immunity. It does not appear to be passively transferable, nor do parasites subjected to the action of serum from immune animals suffer any impairment of their power for producing an infection in susceptible animals. What the nature of this immunity is has been a subject of speculation for some time and little positive evidence is available. It has been suggested that the merozoites fail to gain entry into the red cells through some physical change in, for example, the electric charge or surface tension of this cell, and are consequently phagocytosed, or again that the immunity is of a purely histological nature and that the reduction in the numbers of the parasites is brought about by an enormously increased activity of the cells of the reticulo-endothelial system. That there is a great increase of activity on the part of the cells of the reticulo-endothelial system there can be no doubt, but it is uncertain whether this is *post hoc* or *propter hoc*.

In a paper which will be found elsewhere in this number of the *Gazette*, an investigation into the blood cellular reactions to malarial infection in monkeys has been described. The conclusions drawn in this paper are that the histiocyte response is a reaction to the presence of cell debris in the blood, that, though these cells are able to dispose of large numbers of malarial parasites, they are not by themselves capable of eradicating a malarial infection, and that successful immunity reaction is dependent on an associated monocyte response; as these cells are not voracious phagocytes, the suggestion is that their presence is associated with some humoral change in the serum which is possibly of the nature of an opsonin. However, the positive evidence with regard to immunity in plasmodial infections in general is that it is mainly a cellular response.

These few examples of investigations into the nature of immunity in protozoal infection suggest that these infections are particularly suitable for certain types of investigation, and that, if in the past protozoologists have gained much assistance from general immunological principles mainly worked out on bacterial and spirochætal infections, reciprocity is possible, and that by these or similar protozoal investigations we may add to, or revise, these general principles in such a way as to lead to a better understanding of immunity in bacterial and spirochætal infections also.

THE NEW YEAR'S HONOURS

THE names of medical men and women that appear in the New Year's honours list will be found elsewhere in this number. It is our usual practice to publish the honours list and to congratulate the recipients, but we do not as a rule select any names from this list for special comment. We feel confident that our departure from this rule to make a short reference to the K.C.I.E. conferred by His Majesty the King-Emperor on Major-General J. W. D. Megaw, C.I.E., K.H.P., I.M.S. will not only be forgiven, but will be warmly approved by all of our readers in India.

In the early years of his service in Calcutta Sir John made a great reputation as a physician; at Lucknow, where he was the professor of pathology and principal of the Lucknow Medical College, and later in Calcutta, where he held the post of the director of the Calcutta School of Tropical Medicine for 7 years, he was a most successful and popular teacher; as a medical investigator he has world-wide reputa-

tion, and in each of the two provinces, the Punjab and Madras, where he was head of the medical department, he left permanent marks of his great administrative ability. His appointment as Director-General, Indian Medical Service, three years ago was the natural corollary to his earlier distinguished service and was a surprise to nobody. It would perhaps be out of place, and it is also quite unnecessary, for us to expatiate on the service Sir John has rendered, and fortunately still is rendering, to the medical services and profession in India in this very difficult period.

We ourselves have a special interest in any honour that is conferred on Sir John, because he was for seven years editor of this journal, and we believe that this most successful editorship, during which the journal more than doubled its circulation, cannot be accounted as the least important of the services which he has rendered to medicine and the medical profession in this country. We offer him our heartiest congratulations.

Medical News

THE OPENING CEREMONY OF THE ALL-INDIA INSTITUTE OF HYGIENE AND PUBLIC HEALTH, CALCUTTA

THE All-India Institute of Hygiene and Public Health was to have been opened by His Excellency the Viceroy, but unfortunately Lord Willingdon was indisposed and was unable to attend. The ceremony was performed by His Excellency Sir John Anderson, the Governor of Bengal, in the presence of a large gathering of distinguished visitors, on 30th December, 1932. His Excellency was first introduced to the construction committee of the Institute and then conducted to the large auditorium where the visitors were assembled. Lieutenant-Colonel A. D. Stewart, I.M.S., the Director of the Institute, opened the proceedings by giving a short sketch of the public health policy in Great Britain, which he said had to a large extent provided the inspiration and pattern to other countries in the framing of their public health policies. He then proceeded to discuss the position in India, and of the special place of the Institute in this scheme. He said,

'The opening of this Institute marks a very definite stage in the evolution of public health in India, and it may be interesting on the one hand to trace shortly the events which have led up to its inauguration, and on the other to envisage the part which it is hoped it will play in the future development of public health and state medicine in India. India is at present faced with a coming fundamental change in its constitution and administration. As Sir George Newman has pointed out, development and progress in public health in England have always followed closely on political advancement and change. In India, evolution in these matters has been slower, but we may be assured that, if the present impending changes in India are pregnant with possibilities and opportunities of extended power, responsibility and action to Indians, so will the demands of public health problems for consideration and action become more and more insistent and pressing on the future legislators and administrators of India. Such experience and wisdom and foresight as become

available for general government and administration will also be applied to health problems; for government and public health and welfare are inextricably connected. In envisaging policies and schemes of public health administration in India, we are prone to consider the history of the English system. Though state medical services of the various civilized countries have developed along very different lines, it is interesting to note that the English system has formed the basis of most of these organisations. The English state medical service was first based on the Elizabethan Poor Laws and was at first completely parochial. As the result of the work of Chadwick about 1840, it later became largely centralized. From 1875 began what one may call modern decentralization and a development of the principle of local responsibility, which has gradually developed and which finds definite expression in the Local Government Act of 1929. This Act enlarges and unifies local responsibility in every branch of state medicine and public health. Such decentralization is only possible in a highly organised community, and where public education in health matters has advanced to a point at which the intelligent co-operation of the community as a whole can be counted upon. It is not a principle to be blindly applied as such, but represents a stage of definite development.

The medical officer of health has always been considered the mainstay and prop of the state medical service. The great Public Health Act of 1875 in England made it compulsory on every local authority to appoint a medical officer of health and since 1888 the possession of a diploma of public health has been practically essential. Facilities for specialised training have been available in the British medical schools and universities for over 50 years and have received, particularly lately, special attention from the General Medical Council of Great Britain. Sir John Simon, who served the Local Government Board of England as its Chief Medical Officer from 1855 to 1877, may be taken as the prototype of the English public health scientific official—'always an administrator, never a legislator, forced to carry out his conceptions under the cloak of another's authority;

developing caution and perspicacity in observing trends of thought which provide the security and at the same time the danger of sterility in this sphere to-day.' The spirit of Simon is still that of the successful medical officer of health to-day; contentment with a judicious compromise and the accumulations of small effects in a big result.

Indian public health policy may be said to have commenced in 1857 with the taking over of the civil administration from the East India Company by the Crown. As the result of a Royal Commission appointed in 1860 to enquire into the excessive mortality amongst the civil and military populations, sanitary commissions were appointed in the main provinces. Departmental jealousies and other causes however prevented much being done (except in Madras where the appointment of sanitary inspectors became obligatory in municipalities) and the commissions up to 1906 consisted only of 1 officer who had no staff and few responsibilities or opportunities.

The arrival of plague in Bombay in 1896 awakened the Government of India to its responsibilities and in 1912 a notable advance was made by the giving of grants from central to provincial revenues for the purpose of strengthening the central provincial sanitary staff and for making a start with the provision of district and municipal officers of health. Provinces were allowed to develop their own policy in the appointments of the latter class of officers. Some, like Bengal, adopted the English method of letting local bodies appoint their own health officers, while others mostly appointed a provincialised staff of district and municipal health officers. Provision for instruction and training in health work was meagre and up till 1914 practically all health appointments were held by men possessing British diplomas of public health. While such were suitable for administrative appointments, it was obvious that a training in English conditions could not adequately meet the needs of those actively engaged in practical health problems of Indian districts and towns. The need for such training in India became imperative. Though most Indian universities were prepared to grant diplomas in public health, adequate facilities for training did not exist. In Bengal where district and municipal health officers became compulsory in 1914, temporary arrangements for training were made by the Director of Public Health.

At this time Sir Leonard Rogers was actively engaged in his scheme of establishing a School of Tropical Medicine in Calcutta and his remarkable perspicacity quickly grasped the desirability of including advanced teaching of hygiene in the School of Tropical Medicine. A full-time professor of hygiene was therefore included in the staff of the School, which was affiliated to the University of Calcutta for the purpose of instruction for the diploma of public health. Facilities for special instruction in hygiene were also provided at some other Indian universities.

The Reforms Act of 1919 by removing the advisory control of the Government of India and placing on provincial Governments full responsibility for public health in every respect within the province acted in some respects as a stimulus to Local Governments to enunciate and develop sanitary policies. A few did so, though political dissensions prevented full advantage being taken of this opportunity. In the Calcutta School of Tropical Medicine classes of annual training for the diploma of public health were held and the numbers seeking admission from all over India increased. It became evident that these classes were fulfilling a definite requirement outside Bengal, and that as public health policies and activities developed in India and increasing responsibilities were being assumed by Indians, there should be some institution of an All-India character which would not only train graduates for the University D.P.H. but would provide those already engaged in public health work with facilities for training and for independent higher research. Such an institute would take up investigation in Indian health problems

and questions and would moreover help to co-ordinate public health work all over India and might assist Local Governments and others in any manner possible.

These ideas and possibilities impressed themselves on Major-General Megaw and Major-General Graham, at that time Director of the School of Tropical Medicine and Public Health Commissioner, respectively, and were expressed clearly on several occasions in their annual reports. Dr. Carter of the Rockefeller Foundation during his frequent visits to India was enabled to study medical and public health questions very closely at first hand, especially in their educational aspects. Independently he arrived at the same conclusions as General Megaw and General Graham, and when he found responsible opinion in India in agreement with his, he was enabled to lay before the Rockefeller Foundation his opinions and proposals, which prompted the Foundation to make in 1928 their munificent offer to the Government of India. This offer resulted in grateful acceptance and the first fruits of the Foundation's munificence are seen in this building which is now ready to start its work. On the use which India makes of this Institution will depend its ultimate benefits. India stands now at a new gateway of increased freedom, responsibility, duties and I hope increased health. During the next few years, it will be my duty as Director along with my staff to study and observe the changing conditions and changing systems of administration in India, to devise courses of training and create opportunities for research and methods of practical application of knowledge and research for the development and progress of public health in India. Our success must depend largely on how Indian opinion and Indian administrators face their new opportunities and on the spread of knowledge, and on the growth of responsibility and co-operation in the masses of the Indian people. The opening of the Institute therefore happily coincides with the opening of a new era in the history of India and it would have been very fitting and appropriate that His Excellency the Viceroy who will inaugurate the latter should open the All-India Institute of Hygiene.

It is a matter of great regret that His Excellency the Viceroy is unable to be here to-day owing to illness, but we are fortunate indeed in having your Excellency here to open the building in his absence.

Before asking your Excellency to declare this Institute open I would ask your gracious acceptance of a gold key from Sir R. N. Mookerjee as a memento of this occasion.

Sir Rajendra, whose intense devotion to the promotion of the welfare of his countrymen is well known, has taken a personal interest in the construction of this building much beyond that of his merely being the head of the firm which built it. From the very first the object of the building appealed strongly to Sir Rajendra and for his great personal interest and his practical assistance throughout we cannot thank him enough. I would therefore ask that your Excellency will permit Sir Rajendra to offer you a gold key.

Sir R. N. Mookerjee, K.C.I.E., K.C.V.O., then presented to His Excellency a golden key. Sir John Anderson accepted the key and thanked Sir Rajendra. He continued,

'His Excellency the Viceroy has asked me to convey to you all his great regret that owing to indisposition—not I am glad to say serious but such as to make it imperative that he should stay indoors, he is unable to be present here to-day. In the circumstances he has requested that I should perform in his stead the opening ceremony of the All-India Institute of Hygiene and Public Health. While I fully share the regret that you must all feel at His Excellency's enforced absence, I need hardly tell you that I count it a great privilege to be able to perform this function.

Every important country has in recent years become alive to the necessity for an institution of this nature and, for reasons which have been lucidly explained by Colonel Stewart, India has now wisely followed suit.

This fine building in which we are gathered, the site on which it stands, and its complete equipment, much of which has yet to be installed, represent a munificent gift to India from the Rockefeller Institution—the total value of which amounts to approximately 18 lakhs of rupees. The world-wide benefactions of the Rockefeller Foundation are certainly without any parallel, not merely because of their unrivalled generosity, but also because of the extraordinary care and forethought which is taken to ensure that the best possible use is made of the huge sums which are distributed every year. The members of the Foundation insist on making a thorough preliminary survey of every field of activity in which their help is needed, and, acting on this principle, they sent to India one of their highly skilled experts, Dr. Carter, who made an exhaustive and sympathetic study of medical education in this country. As the result of his report, the Foundation made their generous offer of this All-India Institute of Hygiene and Public Health. What they stipulated in return was that the Institute should serve the whole of India, that the Government of India should undertake the responsibility for the adequate maintenance of Public Health teaching to be organised in six sections in co-operation with the School of Tropical Medicine, and that the Scientific control of the Institute should be entrusted to a Governing Body constituted in such a way as to ensure single-minded devotion to scientific endeavour by a staff chosen solely with regard to its competence. These conditions, far from being irksome restrictions upon the activities of the Institute, are useful safeguards for securing its permanent value to the people of India. The Government of India gratefully accepted the gift and entered into an undertaking to comply with the conditions laid down by the Foundation. It is most unfortunate that owing to the financial situation they have had to start the Institute with four sections only instead of six as was originally intended, but we hope that it will not be long before this deficiency can be made good.

It may be appropriate, ladies and gentlemen, that I should here say a few words about the School of Tropical Medicine and Hygiene which forms the historical background of the new Institute as well as an integral part of the whole scheme. This School stands as a monument to the energy of Sir Leonard Rogers, whose great achievements in combating tropical diseases are known throughout the world. It was expected that his School would provide ample accommodation for the requirements of the teaching and research staff for many years, but the rapid growth of their activities soon showed its Director that a separate Institute of Hygiene was essential for the completion of the scheme. I am confident that history will now repeat itself and I feel that there could be no happier augury for the future of the Institute than the great success achieved by its forerunner—the School of Tropical Medicine. It is indeed gratifying to my Government to find that their action in assuming responsibility for the School has paved the way for the establishment of this organisation, which will supply the needs not merely of Bengal but of the whole of India.

A special word of thanks is due to Major-General Megaw for the unflinching interest and industry with which he has worked for the completion of this beneficent scheme. I wish also to thank all the members of the Constructional Committee for the efficient manner in which they have performed their voluntary task. The work was completed within the specified time and within the estimated cost. In achieving these happy results the Committee were greatly helped by Sir Rajendranath Mukherji, the head of the firm which constructed the building, who, I know, regarded the erection of this Institute as a labour of love rather than as a commercial undertaking.

Colonel Stewart has happily stressed the point that the foundation of the Institute coincides with the opening of a new era in the history of India. India

is now about to enter the gateway to further constitutional advance. Great opportunities entail great responsibilities, not lightly to be discharged, and functions which will influence profoundly the future welfare of the country and its people. But I am confident that the experience gained since the introduction of the Reforms Act and the establishment of Local Self-Government has prepared administrators and legislators for the assumption of the onerous duties that lie ahead of them. Let them remember that good government and the health and welfare of the people march hand in hand. It is not too much to say that the future of this Institute will depend equally upon the wisdom and vision of the administrators of the country and upon the willing co-operation of the people.

India owes an enormous debt of gratitude to the Rockefeller Foundation for their munificent gift and His Excellency the Viceroy bids me assure the Foundation that the Government of India will make the fullest possible use of the gift as a means of promoting the advance of Public Health throughout the land. The Staff of the Institute will, I know, leave nothing undone in the discharge of their duties to fulfil in every way the objects for which it has been established. I have to convey to them, on behalf of His Excellency the Viceroy, his sincere good wishes in the great task that lies ahead of them and an assurance of his continued interest in their welfare.

I now have the honour to declare open the All-India Institute of Hygiene and Public Health.

After this His Excellency made a short tour of the building and departed. The guests were then asked to inspect the building.

THE INDIAN HONOURS LIST

1st JANUARY, 1933

The following are the names of medical workers in the Indian Honours List of date 1st January, 1933. We would offer them our congratulations.

K.C.I.E.

Major-General J. W. D. Megaw, Director-General, Indian Medical Service.

C.I.E.

Major-General W. C. H. Forster, Surgeon-General, Bombay Government.

Colonel J. N. Walker, Director, Medical Department, Nizam's Government.

Lieutenant-Colonel R. B. S. Sewell, Director, Zoological Survey of India.

Kaiser-I-Hind Medal, First Class

Miss Charlotte Rose Greenfield, in-charge, St. Margaret's Hospital, Poona.

Robert Harold Goheen, in-charge of the American Presbyterian Mission Hospital at Vengurla, Ratnagiri District.

Rai Bahadur

Lakshmi Narain Rai, lately Member of United Provinces Medical Service, Benares.

Hargovind Sahai, United Provinces Medical Service, Lecturer, King George's Medical College, Lucknow.

Rao Bahadur

Tinnevely Subba Ayyar Tirumurti, Professor of Pathology, Medical College, Vizagapatam.

Sardar Sahib

Bhai Hira Singh, Civil Surgeon, Campbellpur, Punjab. Pishora Singh, Sub-Assistant Surgeon, Yenangyaung Magwe, Burma.

Khan Sahib

Sayid Wahi-ud-din Haider, Civil Surgeon, Unao, United Provinces.

Rai Sahib

Hridindra Nath Ray, Medical Practitioner, Mymensingh.

Jasoda Nand Srivastab, Civil Surgeon, Basti, United Provinces.

Triugi Narayan Lal, Sub-Assistant Surgeon, Insein, Burma.

Balmakund Naik, Health Officer, Puri Municipality, Bihar and Orissa.

Kalipada Mitra, Assistant Surgeon, Bihar and Orissa.

Subedar John David Bailly, Sub-Assistant Surgeon in-charge of Sind Malaria Enquiry under the Malaria Survey of India, Kasauli.

Rao Sahib

Vengappier Subrahmanyam, Superintendent, Office of Director, Public Health, Rangoon.

Narhar Ramchandra Ghatge, Subordinate Medical Service, Officer-in-sub-charge of West Hospital, Rajkot, Western India States.

Shankar Rangji Jadhav, in-charge of Panwel Dispensary, Kolaba District.

QUARTERLY BULLETIN OF THE HEALTH ORGANISATION OF THE LEAGUE OF NATIONS

Two more numbers (nos. 2 and 3) of this important publication have been received. They contain amongst other matter, two authoritative articles on medical education in France and Germany, respectively. In the first of these two numbers there is a paper on malaria in Siam, a report of a study carried out by the request of the Government of Siam, also the report of the commission on the fumigation of ships.

This publication is one of primary importance to all public health organisations throughout the world, and a copy should at least find its way into the office of every provincial director of public health and port health officers in this country.

KING EDWARD VII'S CONVALESCENT HOME FOR OFFICERS AT OSBORNE

OSBORNE HOUSE, once the favourite residence of Queen Victoria, is situated in The Isle of Wight, between Cowes and Hyde. This one-time Royal residence was given by King Edward, in memory of his illustrious mother, Queen Victoria, to the nation to be converted into a convalescent home for officers of the navy and army; this was at a time when there were only two services. To-day, officers of all three services, as well as of the Indian Army, are received at the convalescent home on the recommendation of the respective directors-general of the medical departments of these services.

The accommodation at Osborne provides for fifty officers, at a very moderate charge, which includes all medical attendance, with such special treatment as massage, diathermy, ultra-violet rays and other electrical treatment, and special dieting. A staff of London consultants pay regular visits, and the mild and equable climate is ideal for convalescents from the tropics. There is a certain amount of accommodation for officers' wives in a private hostel on the estate.

Special features of the grounds are the fine lawns with their tennis and croquet and the picturesque trees, many of which were planted in commemoration of the visits of Royal and illustrious personages. These trees include the magnificent avenue of evergreen oaks at the Royal entrance and Californian pines and other rare trees, all of which are in excellent state of preservation.

Bathing facilities are provided by Osborne Bay, the private beach where Queen Victoria spent much of her time, and circling which a promenade was built to enable her to drive in her pony carriage along the sea front.

There is also a small golf course. In the house there is an excellent library and a billiard room.

We can think of no more ideal place for officers, who have had to take leave from this country on account of ill health, to spend the first few months of their leave. Nobody need be alarmed by the words

'moderate charge'; this is unfortunately an expression which has now been adopted by luxury hotels, but, though we have not any exact figures to quote, we understand that the terms are really moderate and that the impecunious officer going home from this country will find it cheaper than living in a boarding house. In addition he will have all the advantages of a first-class nursing home, combined with those of a 400-acre country club in a glorious situation.

FIFTY YEARS AGO

(From the *Indian Medical Gazette* of February, 1883, Vol. XVIII, p. 47)

PETTENKOFFER's views on the subject of cholera causation are well known, and have frequently been presented and commented upon in this journal. Stated briefly, he holds that certain local and seasonal conditions and individual predispositions are necessary for the effective action of the cholera infection.

* * * * *

He inclines to the belief that the cholera germ is a fungus belonging to the *Schizomyces*, but seeing that their presence is universal, search must be made for a special fungus or for special conditions which confer on an innocent fungus virulent or lethal properties.

* * * * *

After reproducing his early hypothesis he says:—'It may be sufficient to point out that from that time to this I have never found myself in opposition to the parasitic theory; I have striven solely and always against the theory of simple contagion which, in my opinion, is erroneous. I have also endeavoured to obtain for local influences their proper position in epidemiological views, and also to hold out goals of the richest promise to experimental fungology in which I cannot myself take an active part. When I consider the results of the work of the Cholera Commission in the light of the prevailing fungus theory of the present day, I might hold it as most probable, seeing that, as I have before said, cholera is no putrefactive poisoning, that intercourse with places in which the disease is endemic or epidemic spreads an organism (x) which causes cholera in some way unknown to us at present. The poison, however, when brought into other localities without losing its poisonous property, can only propagate itself when it finds in that place a suitable substratum (or nidus) (y), which has its origin in the ground, and serves, so to speak, as nutriment or a host, and which is either already in man himself, or, as seems to be more likely, is in the ground, and from thence attaches itself to dwellings situated on the ground, or to objects to be found therein. Again in cases in which outbreaks of cholera appear to rise without the intervention of the soil, as for example on board ship, the simultaneous presence of the germ (x) and the substratum (y) arising from the land, must be admitted.'

Current Topics

Recent Developments in Immunotherapy

By LAWRENCE P. GARROD, M.B., M.R.C.P.

(From the *Practitioner*, October, 1932, Vol. CXXIX, No. 4, p. 471)

THERAPEUTIC immunization is of two kinds: 'active', bacteria or their products being introduced into the body with the expectation of evoking a state of resistance comparable to that following spontaneous infection; and 'passive', which involves the use of a serum containing already formed those substances by which it is believed that infection is resisted or overcome. Each of these methods is subdivisible, the former according to whether the material used contains actually living bacteria, dead bacteria, or bacterial products; the latter

according to the nature and mode of action of the specific substance in the serum. Some examples of these methods are familiar, others have by no means yet received the general recognition which they deserve. It may therefore be useful to review some of the newer methods, classifying them under the headings already indicated.

ACTIVE IMMUNIZATION

(1) *By means of living bacteria.*—There can be no question that when it is possible to practise immunization by this method, the state of immunity which results is superior to that obtainable by any other. This is to be expected, since the proceeding is the nearest approach to an actual attack of the disease. It is only feasible when the capacity of a micro-organism for multiplying in the body can be greatly diminished; this change can sometimes be effected by exposing it to unusual or unfavourable conditions, whether *in vivo* or *in vitro*. Habituation to a different animal host is an example of the former method, and is the basis of two important and reliable methods of immunization: vaccination against smallpox is inoculation with living smallpox virus which has lost its capacity for producing this disease in the human being by repeated transference among calves, and the prophylactic treatment of rabies depends on the use of living rabies virus reduced in its capacity for attacking man and dogs by passage in rabbits, although here attenuation is secured further by drying the rabbits' spinal cords in which the virus is contained. Among ordinary bacteria, attenuation results from prolonged artificial cultivation, from cultivation in media which, while still permitting growth, contain some inimical substance, and from cultivation under abnormal physical conditions, such as high temperature or pressure; such treatment has been applied in the past to produce living, but nevertheless safe, vaccines for immunizing against anthrax, cholera and typhoid fever.

There is a comparatively new example of this method which has enormous possibilities, although it is still too early to judge whether they will be fulfilled. B. C. G. (Bacille Calmette-Guérin) is a strain of the tubercle bacillus which has been grown since 1908 on a medium containing bile, and has consequently lost much of its capacity for producing disease. Even the guinea-pig, in which inoculation with the smallest numbers of ordinary tubercle bacilli is followed by a progressive and fatal infection, can withstand inoculation with it; a lesion results which is circumscribed, and the animal recovers.

The practice advocated by Calmette is the administration of three doses of living bacilli by the mouth to infants during the first ten days after birth; phagocytosis is believed to take place in the alimentary canal, the bacilli being carried to neighbouring lymphoid tissue and there destroyed. The treatment is undertaken at this extremely early age for two reasons: (1) the bacilli are said to be more readily removed from the bowel during the first fortnight of life, and (2) inoculation, to be effective, must precede natural infection. The treatment has now been applied to upwards of 100,000 infants in France, mainly those born in tuberculous families and therefore exposed to infection at an early age. This is naturally a method of which the results can only be assessed after the lapse of years, and then only with difficulty. From the statistical point of view, Calmette's results to date are said to be unconvincing. From the theoretical standpoint the method is open to two serious objections: (a) that an unmeasurable dose is being given, since the degree of absorption from the bowel and the extent of subsequent multiplication of the bacilli are beyond control, and (b) that the organism itself may be capable of regaining virulence; this aspect of the subject has recently been reviewed by Dreyer.

Nevertheless, the fact remains that living tubercle bacilli have been administered to hosts of children with at all events few untoward results, and that this

proceeding should theoretically secure some degree of immunity. There is certainly at present no more hopeful method of dealing with a disease which has defied forty years of varied efforts at specific therapy. It is not to be forgotten that the immunization of children is only one of two uses to which this method may be put. If it be granted that resistance to tuberculous infection can be increased by means of B. C. G., even were the risks of effective dosage too great to justify its use in infants, there remains the important possibility of immunizing calves among which a small mortality would constitute a less serious objection. The unsatisfactory state of the milk supply in this country and the amount of disease in childhood attributable to this cause have recently been discussed in this journal by Moynihan. There is therefore no need to recapitulate the facts, nor would it be profitable to discuss the merits of pasteurization as a remedy, beyond saying that tubercle bacilli in 'pasteurized' milk are by no means always dead. Viewed from whatever standpoint, the prevalence of tuberculosis in cattle is a grave danger, and if inoculation of calves with B. C. G. can free the dairy herds of this country from tuberculosis, the achievement will be second in importance only to the successful immunization of children themselves.

There are no other established uses for living bacterial vaccines; the method has potentialities of danger which have discouraged its application. It is nevertheless tempting to speculate on the possibilities of treating resistant chronic inflammatory conditions by this method, such, for instance, as long-standing nasal infections due to bacteria which in many cases have little general invasive power, and would therefore not be expected, especially if attenuated, to give rise to any progressive lesion if injected into the subcutaneous tissues. This is a field which remains almost wholly unexplored.

(2) *By means of killed bacteria.*—In the use of ordinary bacterial vaccines, the position remains much as it has been for many years. Reasonably effective prophylaxis can be assured against certain specific infections, such as enteric fever. The comparative uncertainty of prophylaxis for colds and influenza is no doubt largely due to the multiplicity of bacteria concerned, many of which may be represented inadequately or not at all in the vaccine used. If we accept the proposition that some, at least, of these infections are due to a virus, failure is hardly surprising. There is, however, one quite specific infection in which preventive inoculation deserves a wider application, at least until its value can be better appraised; on the appearance of whooping-cough in a family or school, the remaining children may be treated with a *B. pertussis* vaccine with at least an expectation of mitigating the severity of the disease should they contract it. This is a conservative statement in comparison with those of French writers (Pierret), who claim absolute prevention following prophylactic administration and amelioration even if the vaccine be given during the course of the established disease. The discrepancy between these and certain English results, possibly attributable to differences in technique, require that the method should be more fully investigated.

(3) *By means of bacterial products.*—Substances produced from bacteria in a great variety of ways have been used for the purpose of immunization. The method among all these which rests on a sure foundation is the use of soluble toxins. In considering infections from an immunological standpoint a sharp distinction must be drawn between those due to bacteria which produce such a toxin and those which do not or which, at all events, have not so far been shown to do so. In the former, the condition is a toxæmia in the true sense; a demonstrable toxin is produced which is carried to distant parts of the body, whereas the bacteria forming it remain strictly localized in a lesion which in itself may be comparatively trifling; of this type of infection, tetanus is, perhaps, the best example. The outcome of infections of this type depends immediately

not so much on any capacity to deal with the bacteria themselves as on the formation or supply of the antitoxin which will neutralize their toxin. Similarly, preventive immunization must consist in administering not bacteria, but toxin.

It would doubtless be possible to immunize by this method against any of these infections, but tetanus, botulism, gas gangrene and Shiga dysentery are not conditions against which it is usually worth while to secure anticipatory protection. There remain, however, diphtheria and scarlet fever, the former the earliest and most extensively studied of these true toxæmias, the latter admitted to this category only within the last ten years. Susceptibility to either of these infections can be determined by the intracutaneous injection of a small amount of toxin (the Schick and Dick tests) and immunization of those so shown to be susceptible can be carried out by subsequent subcutaneous injections of toxin itself for scarlet fever, of toxin mixed with antitoxin or otherwise modified (since pure toxin is too dangerous) in the case of diphtheria.

It would be out of place here to attempt to review the great volume of work which has been done during the past ten years in attempting to perfect this method. Its objects, especially in the case of diphtheria, have been to evolve a product which will immunize with maximum regularity after a minimum number of injections, which shall be followed by the least possible local and constitutional reactions. The later developments in this direction depend on Ramon's observation that treatment with formalin deprives diphtheria toxin of much of its actually toxic properties without altering its capacity to immunize; this modified toxin, supposed to be identical with Ehrlich's 'toxoid', has been used alone and, more recently, in combination with antitoxin. T. A. F. (Toxoid-antitoxin floccules) consisting of the precipitate obtained when the two are mixed under certain conditions. Of several preparations now available, each may be depended upon to convert at least 90 per cent. of Schick-positive reactors into negatives after a course of three injections which rarely cause even a trivial disturbance.

It is natural to expect that immunity to a grave disease can only be purchased at the expense of an effort on the part of the body which shall entail at least some temporary incapacitation, but, although this is true of some methods of prophylaxis, the price to be paid for immunity to diphtheria is usually no more than the trifling discomfort of the injection itself. That the immunity conferred has adequate permanence is shown by Parish and Okell's re-testing of 440 children from one to seven years after immunization; 95 per cent. were still Schick-negative. Even in the individual who reverts to the Schick-positive condition there is reason to believe that a state almost equivalent to immunity exists, since it has been shown that when once the body has responded to diphtheria toxin, the slightest further stimulus at a later date is followed by the rapid production of antitoxin in considerable amount: in one such case observed by O'Brien, the minute amount of toxin introduced in the Schick test itself had this effect, a second re-test performed later being negative.

Ideally, the universal immunization of young children, at all events among urban populations, is the consequence to which these advances should lead. Public apathy or hostility will probably stand in the way of this development for years to come, and there are still many areas in which facilities for the treatment are not provided. The individual practitioner, therefore, has frequent opportunities of securing protection for individuals, families or communities; that hospital nurses and school children should be tested and, if necessary, treated, is now becoming widely recognized.

PASSIVE IMMUNIZATION

Therapeutic sera are of three chief kinds, of which two are familiar and may be considered briefly.

Antitoxic serums.—In a limited number of diseases to which reference has already been made, the phenomena

of the illness are due chiefly to the absorption from the lesion of a toxin which can also be produced by the growth of the causative organism *in vitro*. Toxin so produced, when injected into animals, excites the formation of an antitoxin which will neutralize very large amounts of toxin, and the serum containing it therefore constitutes a powerful therapeutic weapon, the capabilities of which are accurately measurable. Of the use of these serums in diphtheria, tetanus and some other infections, there is little new that need be said. A rather different and more debatable position exists in connection with the use of scarlet fever antitoxin. We know now that scarlet fever is a streptococcal infection, that the rash is due to the formation of a toxin, that this toxin can be manufactured *in vitro*, can be used for a susceptibility test and for prophylactic immunization just as in the case of diphtheria, and when injected into animals produces an antitoxin. That this antitoxin furnishes appropriate treatment for scarlet fever there is no doubt, but it is being used extensively for the treatment of severe streptococcal infections of other kinds, and its applicability to these is a matter of some difficulty and interest. The 'unitarian' view of the streptococci recently advocated by Okell in a comprehensive review of the part played by these organisms in human disease, regards the hæmolytic streptococci as essentially one race, of which different members vary in their capacity to produce certain effects. Thus, the streptococcus in a case of scarlet fever is one which produces enough of the 'erythrogenic' toxin to cause the rash characteristic of that disease; in septic infection elsewhere, the invasive and pyrogenic activities of the organism predominate, although the red lymphatics sometimes seen in lymphangitis may be taken as evidence that the erythrogenic toxin is also being produced. Scarlet fever antitoxin can do no more than neutralize this one toxin, but assuming that this is produced at least in some amount that all hæmolytic streptococci, its neutralization may just serve to turn the scales in the patient's favour. That life may thus be prolonged and the infection localized in streptococcal septicæmia in rabbits has been demonstrated by Parish and Okell. A preliminary Dick test, where the time can be afforded, is suggested by Okell for distinguishing those cases in which antitoxin cannot be expected to help (*i.e.*, giving a negative result) from those which it may benefit.

It should be added that *Staphylococcus aureus* is now known to produce an exotoxin, and that the antitoxin treatment of severe staphylococcal infections is in the experimental stage; it is too early yet to assess its results.

Anti-bacterial serums.—These are serums containing or supposed to contain antibodies which act on bacteria themselves. In contrast with antitoxic serums, their activity is singularly difficult to estimate, whether experimentally or clinically. The anti-streptococcal serum, to be distinguished clearly from scarlet fever antitoxin (one being prepared by immunizing animals with the organism, the other with its toxin), which was formerly much used in the treatment of streptococcal infection, is an example. Convincing evidence of the efficacy of many of these serums is lacking, and their mode of action is often obscure. In cerebrospinal fever we have one disease which is clearly amenable to treatment with an efficient serum of this type, and it is possible that pneumonia will prove to be another example when the Felton concentrated serum has been more fully evaluated. With this possible exception, no new anti-bacterial serums of certain efficacy have recently been produced.

Convalescent human serums.—A new method having far-reaching possibilities was brought to light when Nicolle and Conseil showed in 1916 that measles in a susceptible subject exposed to infection could be prevented by the injection of serum from a recently-recovered case. Debre, seven years later, was responsible for the observation that when given at a later stage, the effect of the serum was to diminish the severity of the

attack. This proceeding he christened 'Sero-attenuation', and in healthy patients it is preferable to complete protection in that the ensuing mild attack is succeeded by lasting immunity.

The practical opportunities afforded by this method have been discussed recently by Gunn and also by Nabarro and Signy, Stocks; it therefore appears necessary only to recapitulate the main facts. Using the serum of recently-recovered cases, a dose varying from 3 to 12 c.cm., according to the age of the patient receiving it, will protect completely if given during the first five days of the incubation period, or modify the attack if given between the sixth and ninth days. Adult serum, if the donor has had measles in childhood, is effective in approximately double this dosage; whole blood may be given if a parafined syringe be used (to prevent the coagulation of a necessarily rather large amount of blood) and if there be assurance that no other infection is being transmitted by it, an aspect which must not of course be forgotten in collecting and preparing serum. Authorities differ as to the stability of the serum, but on the basis of English experience we may conclude that it can be filtered, treated with preservative and stored for considerable periods without losing its activity. Drying would probably preserve it indefinitely, although this method has apparently not yet been tried.

The ideal treatment of measles in a family where the day of exposure to infection can either be placed accurately or deliberately arranged is unquestionably to give convalescent serum on about the seventh day and thus secure a mild attack with subsequent permanent immunity. On the other hand, when children ill or debilitated from some other cause are exposed to infection, as may happen either in isolated instances or in the ward of a children's hospital, full protection should be afforded by serum given early. Opportunities for using this simple and valuable method of prophylaxis fall to the lot of almost everyone, and it is to be hoped that local authorities in many parts of the country may arrange for the collection of serum from suitable patients, more particularly in fever hospitals, and for its distribution.

The protective power of serum from the recovered subject is a feature peculiar to virus diseases; there is no bacterial infection in which any such striking effect can be obtained, and there are reasons for believing that the protective substance present in such serum differs in its properties and behaviour from any of the recognized bacterial antibodies. The action of such substances has been demonstrated experimentally in a large variety of virus infections and, clinically, in several infections besides measles. In none of these is the clinical evidence of its efficacy equally complete, a fact attributable in part to a difficulty in administering serum at an early stage, and in part to insufficient trial. In poliomyelitis the uses of convalescent serum deserve the fullest exploration: the results obtained in a recent outbreak in Australia are claimed to be satisfactory (MacNamara); success depends on recognizing the disease in the pre-paralytic stage. The results in chicken-pox and mumps are doubtful (Gunn). Encouraging results are reported in post-vaccinal encephalitis (Horder, Hekman), with the serum of a recently vaccinated subject. It is probable that the full possibilities of this method are by no means yet ascertained, and the advantages of using human instead of horse serum need hardly be emphasized.

Summary

A review of the progress of specific therapy during the past ten years calls attention to three important new methods of immunization, each depending upon a different principle. Inoculation with living, but attenuated, bacteria is represented in the use of B. C. G., a method still in the experimental stage, but offering at least some hope of immunization against tuberculosis. Inoculation with preparations of bacterial toxin has been shown to be capable of producing immunity to

diphtheria and scarlet fever. The injection of serum from recovered human cases can be used at will either to prevent or to attenuate an attack of measles, and possibly to modify the course of other infections.

Although these methods can be applied on a large scale only by the action of public health authorities, their employment in individual cases or in small communities remains to a large extent the duty of the individual practitioner, who may find in them the means of performing valuable service.

Recurrent Boils

By RUPERT HALLAM, M.D.

(Abstracted from the *British Medical Journal*,
October 8th, 1932, p. 670)

THERE is a singular disposition to regard the individual suffering from a boil with a certain degree of levity, yet we have it on no less authority than the Bible that 'Satan went forth from the presence of the Lord and smote Job with sore boils from the sole of his foot unto his crown'. Those who have endured the extreme pain of a boil in the external auditory meatus must indeed be tempted to suppose that the same master hand was responsible for their affliction.

To Pasteur is due the honour of demonstrating that the boil is caused by the action of the *Staphylococcus aureus*—a micro-organism which he found also in pus from carbuncles and osteomyelitis—but we are well aware that mere contact between the skin and this organism is not necessarily followed by the development of a boil or carbuncle. The number, the virulence of the cocci, and the degree of resistance of the individual are the determining factors, as in the case of many other infections. Some investigators hold that *Staphylococcus aureus* is not a normal habitant of the skin; others state that every man is a carrier of pyogenic cocci. Investigations of this nature must necessarily be incomplete, for it is impossible to include in the examination the whole skin surface or the contents of the follicles; neither is there at present a satisfactory means of distinguishing between virulent and non-virulent bacteria of the same species. We may, however, assume that most individuals, if not all, are frequent carriers of *Staphylococcus aureus*. The relative number will be influenced by such factors as personal cleanliness and occupation. The personnel of a hospital, for instance, must be constantly exposed to the infection. The age of greatest vigour is that most susceptible to the infection. The highest incidence is amongst males in the second, third and fourth decades of life.

Trauma is no doubt responsible to a certain extent for the selection of these decades. On the other hand, children during the school age are subjected to much trauma, yet the incidence at this age is low, while practical experience teaches us also that sedentary workers are frequently the victims.

The difference in environment and habits of the sexes is hardly sufficient to explain the sex incidence. It therefore appears that the female skin offers a less suitable habitat for the bacteria.

SOME CONTRIBUTORY CAUSES

Some observers maintain that the first boil is the result of an accidental infection, and that subsequent boils are merely consequent infection of the follicles. But boils are not a common complication of other pyogenic diseases, such as sycosis and chronic osteomyelitis, where the skin of the whole body is subject to constant contamination with the *Staphylococcus aureus*. Again, it is notable that persons suffering from furunculosis will often give a history of having had previous attacks of the condition, with intervals of a year or more between. This shows that their follicular resistance to the invasion of the staphylococcus is low. Unfortunately we know little of the immune biological character of the skin. It is true, we are aware, that boils and carbuncles are relatively frequent in diabetes,

yet glycosuria is met with in a very small percentage only of those suffering from furunculosis. An unusual partiality for sweets is sometimes admitted by the victims of the complaint, and a drastic reduction in the consumption of sugar is of great service in the treatment of many cases. A more important ætiological factor which has not received the attention it deserves is the frequent presence, in cases of recurrent boils, of an intercurrent infection on the skin. This occurred in 31 out of 98 consecutive cases examined from this point of view. Thus, 11 were found to be suffering from pruritus ani, 9 from scabies, 4 from impetigo, 2 from pediculosis corporis, 1 from otitis media, 1 from whitlow, 1 from abscess, 1 from oil acne, and 1 from *perléche*.

It is conceivable that any of these coexisting lesions may have been acting as a focus for the staphylococcal infection of the skin. Their recognition is therefore of obvious importance. Another fruitful source of folliculitis and boils is the application of fomentations to suppurating wounds of the skin, the furunculosis often persisting long after the original wound is healed. To avoid this complication it is advisable to restrict the wet dressings to the smallest dimensions. A half per cent. silver nitrate solution may be employed with advantage, for it does not have the tendency to produce a folliculitis of the surrounding skin.

Fortunately the sufferers from furunculosis are usually unaware of the complications which may assail them, yet there are probably more fatalities arising from it than from any other skin disease. At one institution with which I am associated there were, during 1931, four deaths which could undoubtedly be attributed to boils. Of these cases, a girl aged 17 and a man aged 47 succumbed to a boil on the upper lip, a boy aged 16 and a man aged 57 to a carbuncle on the neck. The face and neck are recognized as a danger zone, but, in addition, surgeons meet with perineal and prostatic abscess and osteomyelitis following one or more boils. Any prophylactic measures which may prevent further boils are therefore of very definite importance.

A reduction in carbohydrates is a matter of first importance. That the skin should be kept as dry as possible is a maxim which is supported both by clinical and by experimental evidence. The self-disinfecting power of the skin is influenced by the amount of moisture present. It has been found in experiments with *B. prodigiosus* that these organisms when applied to the skin diminished rapidly in number, particularly during the first ten minutes.

Similar results were obtained when cultures were placed on inert material, such as glass, paper, and hide. The rate of disappearance in all instances was governed almost directly by the amount of moisture present, and the experiments failed to indicate any inherent germicidal power of the skin. These findings are of the utmost importance in view of the fact that the fomentation still reigns supreme as a dressing for boils. Admittedly it is comforting, and also reduces the pain, but at the same time it cannot be too strongly emphasized that it is a common cause of the recurrence—the purulent discharge soaks into the dressing and staphylococci are spread to the neighbouring follicles, where they are encouraged to multiply under the optimum conditions of heat and moisture. My own practice is to recommend the frequent cleansing of the surrounding skin with spirit and the direct application of pads of gauze soaked in spirit as a covering to the boil.

Under the heading of prophylaxis must be considered the advisability of using such measures as vaccine therapy, chemotherapy, yeast, purgatives, etc. There is a wide divergence of opinion concerning these measures. For instance, Sabouraud states that staphylococcal vaccine, prepared according to his technique, rarely fails in subjects less than 50 years of age, and he concludes with the slogan, 'One can, and one must, vaccinate against furunculosis'. On the other hand, his fellow country-man, Clement Simon, holds the

opinion (with which I concur) that vaccines in recurrent boils do not live up to their reputation. Brocq was equally dogmatic in testifying to the virtues of fresh yeast for the malady, for he referred to it as a specific of the same value as mercury for syphilis and quinine for malaria. The yeast he employed may be different to the variety used by brewers in this country; certainly an extensive trial of the latter convinced me that it is useless for the purpose.

It is impossible to discuss the innumerable remedies which have been sponsored, but I feel that my remarks would be incomplete if I did not refer to colloidal manganese hydroxide. I have given it an extensive trial over many years, and I am convinced of its utility. As regards the local treatment, most writers refer to the possibility of averting a boil in its early follicular stage. Puncture with the galvano-cautery, injection of pure carbolic acid, and painting with iodine, each has its advocates, but although some favourable results may be obtained success is by no means the rule.

The treatment of the fully-developed boil is also a debatable subject. Whilst some advocate either excision or incision, others, more conservative in their ideas, allow Nature to take its own course. In either case it is the prophylactic measures taken to prevent reinfection of the skin which are of greater importance.

Common Maladies and Their Treatment Nasal Catarrh

By WM. STUART-LOW, F.R.C.S. (Eng.)

(From the *Prescriber*, November 1932, Vol. XXVI, p. 325)

THE medical mind is clearly made up on the matter of the causation of head colds, namely, that microbic organisms gain a lodgment in the nasal passages, directly or indirectly, being introduced by the finger, applied by the handkerchief, which is often very foul, and constantly inhaled from the respired air, especially in crowded railway carriages. The chief reason, therefore, for the prevalence of nasal catarrh is that ordinary precautions are seldom taken to avoid the spread of the trouble from person to person. So much, then, for the cause and the method of dissemination.

It is well known that many persons are constantly contracting colds in the head—indeed, they are hardly ever free, life being more or less a continuous misery—but it is not so well known that there is a definite reason for this state of affairs, that it is easily remediable, and that such persons are a constant danger to others—their friends in the office and the home, and their fellow-travellers in trains.

The chief cause of this susceptibility to nasal catarrh is an anatomically disturbed nasal interior, due in most cases to an injury sustained when young, sometimes even at birth, sometimes in the football field, frequently in the commonest accidents, such as falls. This explains why one or two members of a family are constantly contracting colds while the others escape; why some members of an office staff are always falling victims while others are immune.

An individual with a normal nasal interior, breathing even a not-too-pure atmosphere, is much less likely to become affected by nasal catarrh than another with a disturbed nasal interior breathing a purer air. To discover the cause of constantly recurring nasal catarrh it is therefore necessary that the nose should be skillfully examined, when some such disturbing factor as has been indicated will almost invariably be discovered. Until it is, and the cause has been eliminated, the person will go on contracting head colds to his own great discomfort and the jeopardy of everyone coming in contact with him.

It is not the person unvaccinated against colds who contracts and spreads nasal catarrh so much as the individual with the internal anatomy of his nose disturbed who is so vulnerable to nasal congestions. He is a veritable microbe generator, and a bacterial

disseminator in every coughing spasm and sneezing attack to which he is liable.

The inferior turbinal may be taken as criterion of a healthy nose, and it will be found to be a very correct standard to go by in the study of departures from the normal. The two entrances of the nose should be symmetrical and sufficiently patent to allow of a free ingress of air on both sides: this is of the greatest consequence, since any obstruction at the very entrance to the passages, such as collapse of the alar cartilages, or dislocation of the columellar cartilage into the entrance, by lessening the volume of the air current, directly leads to congestion and accumulation of discharge and so to nasal catarrh. If these seemingly simple and visible defects are not remedied, it avails but little to perform some skilful operation on the nasal interior for the removal of catarrh, as it will inevitably be a failure. The nasal septum should be straight; but it seldom is, although slight departures from the normal are of little consequence as a reason for the origin of catarrh. The inferior turbinals, easily visible on tilting the tip of the nose with the thumb, are normally rosy-red, rotund, resilient, and moist, and a free passage can be seen between their most prominent parts and the septum.

The commonest departures from the normal, as seen best in the inferior turbinals, consist either in exaggerations or the contrary of these healthy conditions. In chronic rhinitis the inferior turbinals are too rosy-red, too rotund, too resilient, secrete too much seromucous discharge, and the nasal passages are diminished and partially blocked, especially on lying down. In hypertrophic rhinitis the turbinal is enlarged but more firm in its consistency, less rosy-red and resilient, but nevertheless characterized by over-secretion. In atrophic rhinitis the turbinal is non-existent or very small, and is usually covered with septic crusts. The middle turbinal in the normal nose is usually easily seen on tilting the head a little backwards, and is rosy-red, uniform, smooth, and moist. The floor of the nose can be readily inspected from the front and is seen to be straight and concave, and should not contain any discharge. The nasal septum may be found more or less deviated to one or even both sides when there is a somewhat double deflection—to one side in front and to the opposite side farther back; or one or more spurs may be discovered projecting from one or both sides of the septum.

Two very common and yet often long undiscovered causes of chronic nasal catarrh are nasal polypi and involvement of the maxillary antrum. These may keep up a more or less constant nasal catarrh which baffles the physician's many efforts to remedy.

One of the commonest causes of a persistent nasal catarrh is the presence of mucous polypi in the nose. These are at first very small; they nearly always spring from the region of the middle turbinal, and hang free into the middle meatus. They also often start on the lips of the hiatus semi-lunaris, on the outer wall where the mucous membrane is rather loose and easily becomes congested and œdematous. The discharge is frequently of a watery character, and until the polypi cause blocking of the middle meatus this may be all that patients complain of, except that changes in the weather affect them—dry weather favourably, and wet unfavourably—as regards the amount of stoppage and discharge.

Nasal catarrh, generally with a fetor and a thick yellow discharge, is how nearly all patients suffering from chronic antral disease describe their complaint. On examination pus is seen on the floor of the nose and can generally also be detected running over the inferior turbinal and down under the middle turbinal. If this discharge is wiped away and the patient's head lowered and inclined to the opposite side for ten minutes so that the affected antrum is uppermost, on raising the head and again examining, pus is usually again to be found in these positions. Transillumination will show the maxillary antrum to be dark on the side

involved; and, if the inner wall of the antrum be punctured with a small trocar and cannula, pus can be blown and washed out, which, of course, is proof positive of septic antritis.

The treatment of nasal catarrh obviously depends upon the cause: it is therefore imperative to ascertain its source. Certain common rules apply to the treatment of all nasal discharges, and these should on no account be overlooked. It seems to be almost an instinct in the medical mind to start the treatment of nasal discharges by ordering syringing, and I am particularly desirous of giving warning against the danger of such measures. A sniffing nasal douche may be used, or a warm, soothing alkaline lotion might be sniffed into the nostrils from the palm of the hand with safety and advantage. Nothing more forcible than a gentle sniff of such a liquid into the nose is warrantable. Where the desire is only to clear and moisten the nasal passage, a prescription such as the following is good:—

Sodium chloride	45 grains
Sodium salicylate	45 "
Borax	90 "
Potassium chlorate	60 "
Glycerine	60 minims
Menthol water	to 6 fluid ounces

Of this mixture two teaspoonfuls should be added to two ounces of warm water and used to spray or sniff up the nostrils occasionally.

When fetor is present, a solution containing phenol, 1 grain, and sodium bicarbonate, 4 grains, in 1 fluid ounce of warm water is recommended. Sodium sulphate, 20 grains to the ounce, is also advantageous for dissolving away purulent discharge.

All lotions applied to the inside of the nose should be lukewarm; cold applications are never advisable. No irritating remedy should ever be used, as anything producing irritation rapidly induces congestion and obstruction by causing turgescence of the lining membrane.

In most cases of nasal catarrh after the discharge has been thinned, moistened, and partially removed by a suitable soothing lotion, the application of a soft ointment is very gratifying to the patient, as it protects any excoriated or abraded surface and prevents crusting of the discharge. No irritating constituent must ever be introduced into such ointment; individuals differ greatly in the sensitiveness of their nasal lining. It is always best, therefore, to begin with a very weak composition, such as 4 grains of menthol and 20 minims of oil of eucalyptus to one ounce of yellow soft paraffin. Two to four grains of cocaine (alkaloid) may be added should there be much congestion or sign of inflammation. Should the trouble lie in the middle turbinal region or above and behind it, an anterior nasal atomizer may be used. By this means the same ingredients, but in slightly stronger proportion and dissolved in liquid paraffin, may be made to reach the higher parts of the nose.

It is of supreme importance that these recurrent acute catarrhal attacks should be prevented, and certainly never be allowed to drag on or frequently recur. For, just as the parallel case of acute middle-ear catarrh, if not promptly treated by paracentesis, will lay the foundation of chronic suppuration of the middle-ear, so a neglected acute or chronic nasal catarrh frequently results in sinus infection, sometimes acute and sometimes chronic, thus establishing chronic nasal catarrh.

Hay fever is not by any means the best name that could be given to a condition which consists chiefly of a more or less sudden onset of watery nose-running with headache and sneezing—serous and sero-mucous nasal catarrh. Some persons are, undoubtedly, especially liable to nasal catarrh when grass-pollen dust is about, but the nasal interior, even in such persons, has been ready for the paroxysm, the lining membrane being chronically congested from the presence of some disturbance of its anterior anatomy, such as enlargements, deviations, spurs, polypi, or adhesions. Attacks often

cease after operation on such irregularities. This is the true explanation of so-called special susceptibility. Just as some people have very irritable skins, so some have a very sensitive nasal lining, and the inhalation of very little dust will bring about the symptoms commonly grouped under the name.

Those liable to acute nasal catarrh should frequent sea-side places when hay-making is going on; or, better still, if possible, take a sea voyage. In this way, by simply avoiding dust in any form in the inspired air, attacks may be prevented. A soothing application such as warm soft paraffin painted into and sniffed up the nostrils, thus coating the lining, will often prevent an onset; or, better still, plain liquid paraffin (light gravity) blown into the nose from an anterior nasal atomizer will ward off an acute rhinitis in the same way.

I have found useful the administration of phytin, containing as it does calcium and phosphorus which restore a want in the blood. It should be continued regularly for a few weeks. One-tenth of a grain of parathyroid is also helpful. Milk freely added to the diet, if otherwise advisable from a digestive point of view, is helpful in increasing blood-calcium. Anemia should be treated, and constipation suitably remedied. The blood-pressure is almost always too low—a blue congested nose, cold hands and feet, and complaint of feeling chilly being usual. In such aggravated cases I have found solution of adrenaline hydrochloride, 4 minims, three times a day, of the greatest assistance, even a few doses quickly restoring pressure equality, and giving a feeling of well-being and equanimity. This can be continued a few days at a time and will become a distinct help towards both treatment and prevention.

Locally the treatment of an attack must be essentially soothing, and after trying many different preparations I have resumed the use of cocaine: a warm 5 per cent.

aqueous solution of cocaine hydrochloride should be freely sprayed up the nostrils from a fine spray, and pledgets of cotton-wool soaked in the solution placed over and under the turbinates and left in position for five minutes. In persons specially susceptible to cocaine, 3 per cent. will suffice, and this alone will be enough to give relief after a few minutes. Should there be much diffuse turgescence of the lining, or even only patchy distribution of turgescence, it is best to use a cocaine solution mixed with equal parts of adrenaline solution and normal saline.

On the withdrawals of the plugs the inside of the nose should be carefully examined for departures from the normal, such as spurs, ridges, etc. In this way it may be ascertained whether these are likely exciting centres for the trouble, and if so, whether in the intervals of acute onsets these should be operated upon. Such congested locations so liable to sudden turgescence on even slight irritation from dust, cold air, etc., are suitable places for the application of the galvanocautery, but only when the acute attack has subsided.

The patient should have an anterior nasal atomizer containing plain liquid paraffin, and this should be freely used before going out in the air, as it acts as a protection to susceptible, sensitive mucous membrane. On no account should cocaine be ordered: it should be used only by the rhinologist and never given for the patient's own use.

The physician is often asked to say how head colds may be prevented, and he is sometimes reflected upon because his measures are futile. Patients, however, should be reminded that they must themselves fully and rightly carry out their part by trying to attain exemption. They must remember such simple measures as to keep warm, to shun crowded places, to get into their overcoats, and to keep their mouths shut when passing from heated rooms to the open air.

Reviews

A SHORT HISTORY OF BIOLOGY: A GENERAL INTRODUCTION TO THE STUDY OF LIVING THINGS.—By C. Singer. Oxford: At the Clarendon Press, 1931. Pp. xxxv plus 572, with 194 illustrations. Price, 18s.

MANY foolish things have been said by American millionaires and many of their statements, both foolish and wise, have received a considerable measure of publicity, but no one has achieved such heights in either foolishness or notoriety as Mr. Ford with his classical remark, 'History is bunk'. This same theme has been developed and satyriized by a brilliant English writer; he has painted a world for us in which all history has been banished, all books prior to a certain date destroyed; only the present and the future are considered of account. It is a safe world in which everything is ordered and nothing is left to chance. Specialisation has reached a degree of perfection. A man is not only trained from his infancy to fit him for one particular occupation all his life, but he is procreated (in a bottle) with that object. It is difficult to find flaws in this writer's argument, but one is supplied by the author of the book under review; he has shown how specialisation, if developed to its logical conclusion, must eventually lead to the death of scientific advance. The work by scientific specialists is so intricate and abstruse that it is often impossible for the general reader to understand it. It is not merely a matter of the use of technical expressions; it is impossible to convey the ideas in any language to a mind not specially trained to receive them. The process of learning more and more about less and less will continue until eventually no specialist will be able to understand the results of any other specialist's work; thus no specialist

will have a scientific heir and each specialist's life-work will die with him.

It is obvious that far more liaison between different scientific specialists is necessary. It is not very clear how this is to be brought about; many general scientific surveys have been written, but they are on the whole unsatisfactory. Charles Singer considers that the historical method of approach is most satisfactory. The book under review is his justification for this contention, and incidentally a complete refutation of Mr. Ford's dictum. He has traced the advance in biological knowledge from the times of Hippocrates and Aristotle to Galen, then over that amazing blank of a thousand years, the dark ages, to the times of the re-birth of scientific enquiry in the thirteenth century, through its early stages of slow advance which has gradually accelerated during the last six or seven hundred years until the rate of progress of knowledge has reached the alarming speed of the present day. The scientist of the six hundred years ago was a universal scientist, he knew something about everything that could be called scientific, and it is only during the last century or so that specialisation began to develop to produce the myopic scientist of the present day.

Written in a very pleasing style it is an extremely easy book to read. The author has managed to use language that anyone with an ordinary education can understand but which is not irritatingly kindergarten. It is a book that every 'specialist' should be compelled to keep in his library, and yet it is one that anybody could read again and again with pleasure and profit.

It is only necessary to add that the book is published by the Oxford University Press.

L. E. N.

MEDICINE: ESSENTIALS FOR PRACTITIONERS AND STUDENTS.—By G. E. Beaumont, M.A., D.M. (Oxon.), F.R.C.P., D.P.H. (Lond.). London: J. & A. Churchill, 1932. Pp. xvi plus 719, with 61 illustrations. Price, 21s.

DR. BEAUMONT'S book, *Essentials of Medicine*, has been eagerly awaited by those physicians who practice general medicine. The author, in collaboration with Professor Dodds, was responsible for *Recent Advances in Medicine*, which achieved such enviable notoriety and which, in its many editions, provided for years, a concise, clear and up-to-date account of modern medical work.

The present book is the outcome of five years labour and the result is a book of outstanding merit. It is a complete index of modern medicine in concise form. The attempt to serve both the student and practitioner is always fraught with difficulty, but we have nothing but praise for the manner in which Dr. Beaumont has carried out his difficult task.

The book is, in reality, a synopsis of medicine and there are few known medical conditions that do not receive mention. Each heading is followed by a short but up-to-date account of clinical findings and treatment. If one were inclined to criticise, one might say that the headings were too numerous, and the descriptions of the more important conditions and their treatment too sketchy. If however Dr. Beaumont had made his headings less numerous the book would have been incomplete; if he had made his descriptions more detailed it would have become too bulky. We think he has carried out a very difficult task, that is a complete survey of modern essential medicine, with consummate skill and ability and we have no doubt a copy will find its way into the library of every progressive physician.

We would especially pay tribute to the section on diseases of the nervous system. This section is a model of lucidity and is well provided with excellent plates of illustrations.

J. D. S.

MEDICINE: ANALYTICAL REVIEWS OF GENERAL MEDICINE, NEUROLOGY AND PEDIATRICS. September 1932, Vol. XI, No. 3. Baltimore, U. S. A.: The Williams and Wilkins Company. (English Agents are: Baillière, Tindall and Cox, London.) Price, 21s. per volume and postage 2s. 6d. Single copy: 6s. 9d.

THIS last number of *Medicine* is yet another useful publication which will be of great interest to members of the medical profession. It contains three extremely instructive articles; the first and the chief article deals with syphilitic optic atrophies; a subject regarding which our ideas are still in a very confused state. The author of the article has given a well-considered and critical digest of the whole medical literature on the subject and has offered his own conclusions and opinions on many clinical and pathological phenomena. The treatment aspect has received particular attention, various techniques of treatment being described. The rôle of arsphenamine, and other important anti-syphilitic remedies has been very thoroughly discussed. Arsphenamine intravenously, bismuth, mercury and the iodides, in any combination or for any length of time, have all been shown to be useless. Sub-dural treatment with arsphenaminized serum or neoarsphenamine injected intraspinally or intracranially are the treatments advocated. Fever therapy, chiefly with malaria, has been considered to be still in the experimental stage.

The second article represents the Harvey Lecture on experimental epidemiology by an expert in public health. The subject is rather abstruse, but will be very informative to those interested in the transmission problems of various bacterial and microbic diseases. The third article on factors concerned in the evacuation of the gall-bladder is particularly valuable to the

physiologists. It contains much useful data which will guide the clinicians in their treatment of jaundice and other obstructive manifestations of gall-bladder trouble. This journal should greatly appeal to the practitioners and those engaged in post-graduate study.

R. N. C.

INTERNATIONAL CLINICS.—Edited by H. W. Cattell, A.M., M.D. Vol. II, Forty-second Series. London: J. B. Lippincott Company, 1932. Pp. viii plus 307. Illustrated. Obtainable from Messrs. Butterworth & Co. (India), Ltd., Calcutta. Subscription Rs. 37-8 per year. Price, Rs. 9-6 per volume.

INTERNATIONAL clinics is a collection of a series of lectures on clinical and general medicine, surgery and other allied subjects. The book contains contributions from leading members of the medical profession throughout the world and is a very useful publication. The present volume belongs to the 42nd series and bears the high standard of the previous numbers. It consists of ten sections. The first deals with biochemistry and fully discusses the recent application of Claude Bernard's theory of anaesthesia. The second section deals with the surgical diagnosis, indications and safeguards for the operation of hernia, and dietary as a therapeutic measure. The author points out the importance of careful taking of history and physical examination in the diagnosis of disease, and emphasizes that radiography, microscopy, etc., should be only used as confirmatory aids. The sections on ulcerative endocarditis, recent progress in surgery, light-therapy and progress in paediatrics are lucid and brief, and will be of special interest to practitioners. The book is written in a simple and easy style, and forms very light reading, although it is full of information concerning the recent advances in the realms of medicine. At the end of each chapter a bibliography of interesting papers is given for those who want to have further information regarding different subjects. This volume will be very useful to senior students, practitioners, and to those taking up post-graduate work.

R. N. C.

'INTERNAL MEDICINE: ITS THEORY AND PRACTICE.'—Edited by John H. Musser, B.Sc., M.D., F.A.C.P. London: Henry Kimpton, 1932. Pp. xi plus 1316. Illustrated. Price, 50s.

THE addition of yet another book on medicine to the already large and overflowing library of books on the subject may appear superfluous to many readers. The book under review, however, is a little different from the ordinary textbook and presents several important features which will not fail to be noticed by careful students. The chapters are contributed by a group of twenty-seven authors—all teachers of repute in America, who can speak with authority on the subject. With the increasing length and complexity of the medical curriculum and the consequent need for specialisation in different branches of medicine, no one man can deal satisfactorily with the whole subject, and it is only proper that different sections should be entrusted to those possessing special knowledge in individual subjects.

All the chapters have been well written. Most of the chapters are preceded by a discussion of the general features common to the group of diseases dealt with in that section. This gives a wide outlook into the nature of the problem and is conducive to better and clearer understanding. The infectious diseases have been grouped under the various causative organisms and are not grouped together under the generic term of fever as is the case in many other books. The section dealing with the diseases of the blood is full of new terms and should specially interest the reader. The structure of the bone marrow and the mechanism of production of anaemia have, however, been meagrely dealt with. Avitaminosis, and pulmonary tuberculosis

are sections which are particularly well done. Like many other American books, it is not unwieldy. It is written in that racy, pleasant and readable style which characterises the American publications. The printing and format leave nothing to be desired.

R. N. C.

WHEELER AND JACK'S HANDBOOK OF MEDICINE.

—Revised by John Henderson, M.D., F.R.F.P.S. (Glas.). Ninth Edition. Edinburgh: E. & S. Livingstone, 1932. Pp. xix plus 654. Illustrated. Price, Rs. 9-6. Obtainable from Messrs. Butterworth and Co. (India), Ltd., Calcutta.

The original edition of this work appeared in 1894 and it is proof of its popularity that the book has now reached the ninth edition.

A handbook, as pointed out by the author, is not a textbook and cannot be expected to contain the same amount of substance. At the same time, it should have certain attributes peculiar to its own class. It must be a complete, concise, though naturally not exhaustive, review of the subject, assembled in a volume of such a size that it may be the constant companion of the student both at the bed-side and elsewhere. Further, as it is intended for the fledgeling, the subject-matter must be presented in predigested and assimilable form. In fulfilling these essentials, the author has been conspicuously successful, and there is no question but that the new edition will gather to itself a host of friends and that a large number of students will find it invaluable both at the outset of their careers and during the revision period before examinations.

In this book the author has exercised a rigid economy in words and space, but has amplified and made the text more clear by the inclusion of tables, both of diagnosis and classification, and of a number of instructive diagrams.

A valuable feature is to be found in the preface to each main subject giving not only a description of the relevant anatomy and physiology, but also a careful consideration of the signs and symptoms to be found at the bed-side, together with details of such laboratory methods as may be necessary.

Reviewers have from time to time in these pages advised that, in works of this size, the subject of diseases exclusively confined to the tropics should be left out. In this instance, we endorse that view. Not only is the space allotted too small to allow of the conveyance of any clear impression of the disease described, but also, in many instances, the opinions expressed are by no means in accordance with the experience of those who deal with such diseases at first hand: for example, we cannot regard puncture of the liver as a legitimate first step in the diagnosis of kala-azar, nor is gangrene of the nose a standard complication in cholera.

To turn to other matters, we might venture to appeal for a revision of the chapter on rheumatic fever, in the next edition. In the present chapter all mention of the equally important and insidious rheumatic infection of young children is confined to three lines. Further, we should like to see the section on chorea removed from its present surroundings and included in a chapter entitled 'rheumatic infections'.

F. H. V. H.

'TUBERCULOSIS OF THE LUNGS.'—By S. L. Piplani, B.Sc. (Hons.). London: John Bale, Sons and Danilesson, Ltd., 1932. Pp. 205. Illustrated. Price, 15s.

IN a preface, Mr. S. L. Piplani states that the object of writing this book is to give information to those who are suffering from, or are apprehensive of, pulmonary tuberculosis. While calling the book semi-popular, the author has dealt with such subjects as anatomy, physiology, embryology, and pathology. Obviously, such a book cannot be styled 'semi-popular'.

The book has been divided into two parts. The first part deals with the theory of pulmonary tuberculosis and it is doubtful if this part will interest very much the general reader for whom the book is primarily intended. The reader will not be interested to know that the volume of air in the lungs consists of tidal air, complementary air, and residual air, that tuberculosis in the parrot is caused by the bovine type of tubercle bacillus, or that the lungs grow from the fore part of the alimentary canal. What he would like to be told is the way in which infection takes place in the body, the symptoms he should look for, and the way he should live to get rid of the trouble.

The theory of immunity has been discussed rather elaborately and will not be of much use to the average reader. The author is under the wrong impression that in tuberculosis the percentage of lymphocytes is higher than usual. He is not aware of the recent work that has been done on leucocytic reactions in pulmonary tuberculosis which shows that the monocyte represents tubercle formation, the neutrophil represents tubercle undergoing abscess formation, and the lymphocyte represents the healing phase of the tuberculous lesion.

The second part of the book deals with treatment and will be of some interest to the reader. Morphine has been referred to by the author as an 'heroic' measure that is employed for 'obstinate and recurring cases' of hæmoptysis. Morphine has no direct action on hæmoptysis; it helps indirectly by giving mental rest to the patient which is no less important than physical rest, and it also allays unnecessary cough. Morphine is never intended to be given as a 'cure' for hæmoptysis.

A long chapter has been devoted to the function and use of tuberculin. Tuberculin has been given extensive trial and found wanting. Its use in treatment on any large scale is not in evidence anywhere now—not even in its home, Germany.

In the chapter on Sanocrysin and allied products, the author has unnecessarily gone out of his way to criticise the Ayurvedic system of medicine as being unscientific and based on empiricism.

Treatment by artificial pneumothorax was suggested for the first time in 1822 by James Carson of Liverpool, and not by Forlani and Murphy who were not Englishmen as the author seems to believe. The results obtained from thoracoplasty are far from discouraging as the author says when it is remembered that the operation is performed in cases who have failed to improve under other methods of treatment and have been given up as hopeless.

There are many inaccuracies in the book which has been made too technical to be of much use to the popular reader. It contains a collection of case results drawn from various sources and a number of illustrative diagrams. We did not observe many misprints in the book, but surely when the author refers to a sanatorium at 'Bhaoli' he must mean 'Bhowali'.

Y. G. S.

SYNOPSIS OF THE BRITISH PHARMACOPOEIA, 1932.—By H. W. Gadd. Twelfth Edition. London: Baillière, Tindall and Cox, 1932. Pp. viii plus 162. Price, 3s. 6d.

THE publication of a new pharmacopoeia is a matter of considerable importance to all who are engaged in the profession and trade of healing. A new British Pharmacopoeia was published in 1932.

A pharmacopoeia is primarily a means of providing a basis of understanding between the physician who prescribes and the pharmacist who dispenses the medicine, so that when any medicine is prescribed by name the dispenser will know exactly what is required. In the new pharmacopoeia a number of changes have been made; when a physician is prescribing, it is of importance that he should be fully aware of these changes, as unless he specifies 'old pharmacopoeia' on his prescription the dispenser will almost certainly make

it up on the new standards, and his patient will not be getting the exact medicine he wished him to get. For this reason it is very important that all concerned should acquaint themselves with the new work on the earliest possible occasion. For the busy practitioner this is rather a formidable task. Furthermore, he cannot carry with him the large volume of the new pharmacopœia, but he will find that this synopsis will fit into the smallest of waistcoat pockets, without appreciably distorting the most tight-fitting of coats.

The synopsis gives a full list of the drugs now included in the new pharmacopœia, with the dose, both in the imperial and in the metric systems, a few words on the characters of each drug, and a few more words of detail in the 'remarks' column. These details will be found quite sufficient for any prescriber.

There is in addition a separate list of new drugs which were not included in the old pharmacopœia, another list of drugs which appeared in the old pharmacopœia but are not in the new one, a list of drugs whose names have been altered, and, finally, a list of those whose composition has been altered. A comparison of the lengths of these lists is of interest; the new preparations, amongst which we notice 'totaquina', fill four columns, whereas the exclusions fill eleven columns. (It is very encouraging to think that the medical student will gain a little relief in this direction from his ever-increasing burden.) The list of altered names fills $3\frac{1}{2}$ double columns whereas the drugs of altered composition fill only just over one column. Amongst the 'axed', many of us will see old friends departing; all the decocta and all the vina have gone, and the unguenta seem to have suffered heavy losses.

There is much other valuable information in this minute volume.

THE EXTRA PHARMACOPŒIA OF MARTINDALE AND WESTCOTT. Twentieth Edition. Volume I. By W. H. Martindale, Ph.D., Ph.Ch., F.C.S. London: H. W. Lewis and Co., Ltd., 1932. Pp. xlviii plus 1216. Price, 27s. 6d.

THE first volume of the twentieth edition of the extra pharmacopœia has just been published. The book is so well known that it scarcely requires any special introduction to members of the medical and pharmaceutical profession. It was first published in 1883, just 50 years ago and has ever since held a most unique and privileged position in the medical and pharmaceutical libraries. The progress of medical chemistry and pharmacology has been phenomenal since the first edition was written and the pages have had to be frequently revised, rewritten and added to. The first volume contained only 313 pages. Since 1912 the subject-matter has grown to such an extent that it was thought desirable to divide it into 2 distinct volumes. The first volume of the twentieth edition alone contains 1215 pages excluding the introductory pages and the second volume is expected to have another 800 pages. This in itself shows that the book has kept itself abreast of the modern advances. The original scheme has, however, been largely retained and those who used to refer to the old volumes constantly will not find it difficult to find what they want at a glance. Though the edition has come out practically simultaneously with the new British Pharmacopœia, all the changes therein have been fully incorporated and a synopsis of the alterations, in tabular form, has been appended. Apart from the valuable references to the original papers with regard to various drugs and chemicals, the pharmacists and the drug-store proprietors will find the various laws and regulations for keeping, dispensing and selling poisons of great use to them. The Therapeutic Substances Act with the latest regulations published in 1931 is also given. The book is one without which no medical library can afford to carry on.

R. N. C.

AIDS TO SURGICAL DIAGNOSIS.—By C. P. G. Wakoley, F.R.C.S. (Eng.), F.R.S. (Edin.). Second Edition. London: Baillière, Tindall and Cox, 1932. Pp. vii plus 172, with 6 figures in text. Price, 3s. 6d.

THIS book is in the well-known students' 'Aid' series. It is very concisely written without waste of words. Points of importance are duly emphasised and easy of reference. It should prove of great value to the medical student and also to the busy practitioner.

A. H. P.

A SHORTER SURGERY, Third Edition. A Practical Manual for Senior Students.—By R. J. McNeill Love, M.B., M.S. (Lond.), F.R.C.S. (Eng.). London: H. K. Lewis & Co., Ltd., 1932. Pp. viii plus 414, with 96 illustrations. Price, 16s.

THIS book has been written for the medical student and the more important principles of surgery have been condensed and crystallised as much as possible. No attempt has been made to cover the whole field of surgery, but only that aspect of it which is necessary for qualification examinations.

The various diseases and surgical conditions are rigidly classified, but sometimes rather at the expense of pathological accuracy. The whole subject of burns is dealt with in one page in the chapter devoted to surgical pathology, although the pathology of burns is not discussed.

Infections of the fingers and hand are not mentioned, yet two whole pages of small type are devoted to Spiller's operation for section of the antero-lateral tracts of the cord. This with a number of other operations which are described in detail has surely no place in a *shorter surgery*.

On the whole however the matter is sound and concise. The illustrations are good and appear in most instances in close relation to their appropriate text.

Students will certainly obtain much useful information and help from this book, provided it is read in conjunction with, and not instead of, their surgical textbooks.

A. H. P.

INTRACRANIAL SUPPURATION.—By E. M. Atkinson, M.B., B.S. (Lond.), F.R.C.S. (Eng.). London: Jonathan Cape, 1932. Pp. 127. Price, 5s. Obtainable from Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 3-12.

'INTRACRANIAL Suppuration' is one of the Modern Treatment Series. It is a small volume of 124 pages. There are six sections—general pathology, prevention of intracranial complications, osteomyelitis and extradural abscess, infective thrombosis of the venous sinuses, meningitis, and brain abscess. The author remarks in the preface that it has not been an easy book to write. He has, however, admirably succeeded in bringing a vast amount of scattered work within the compass of this small volume.

The chapters on infective thrombosis and brain abscess are particularly good. In the latter, the desirability of operating without waiting for localising signs is emphasised. The style is simple—almost conversational in places—and the subject is clear and eminently practical. The book is extremely handy and the printing excellent.

S. A. McS.

'THE PRINCIPLES AND PRACTICE OF OTOTOLOGY.'—By F. W. Watkin-Thomas, F.R.C.S., B.Ch. (Camb.), and A. L. Yates, M.C., M.D. (Lond.), F.R.C.S. (Edin.). London: H. K. Lewis and Co., Ltd., 1932. Pp. xli plus 568, with 199 (5 coloured illustrations). Price, 25s.

THIS new volume on a specialised subject will appeal to its intended readers—the young doctor taken to the D. L. O. or other higher degrees, and the general practitioner surgeon.

It is well written and the numerous illustrations and line drawings are clean and well reproduced.

The authors have drawn on a wide field for the contained material and have given a clear, well-balanced and up-to-date account of the subject. There are copious, easily-accessible and recent references throughout the book, which add greatly to its value.

F. H. B. N.

'DISEASES OF THE NOSE, THROAT AND EAR.'

By A. L. Turner, M.D., LL.D., F.R.C.S.E. Third Edition. Bristol: John Wright and Sons, Ltd., 1932. Pp. xxvi plus 465, with 250 illustrations in the text and 19 plates, of which 8 are in colour. Price, 20s.

THIS excellent book requires no recommendation. Written in clear style and based on the sound and conservative teaching of the Edinburgh school, it should be in the hands of every practising medical man. For the student it is a trustworthy guide and to the practitioner a tried and proved friend.

Much new matter and many new illustrations have been added in this edition, bringing it thoroughly up to date, without unduly enlarging the size of the book or increasing the price.

The editor, collaborators and the publishers are to be heartily congratulated on their production.

F. H. B. N.

'SOUND CONDUCTION AND HEARING.'

By A. Zund-Burguet. Translated by MacLeod Yearsley, F.R.C.S. London: John Bale, Sons and Danielsson, Ltd., 1932. Pp. 139. Price, 8s.

ENGLISH-SPEAKING otologists owe McLeod Yearsley a profound debt of gratitude for his scholarly translation of Mr. Zund Burguet's book. This volume should do much to popularise his electrophonoid method of re-education for deaf ears and to dispel a considerable voice of criticism against this method of treatment which has brought back hearing to so many sufferers.

We can recommend it to all, supporters and sceptics alike.

F. H. B. N.

A RADIOLOGICAL STUDY OF THE PARA-SINUSES AND MASTOIDS.

By A. Granger, K.C.B., K.C.I., M.D., F.A.C.R. London: Henry Kimpton, 1932. Pp. 186. Illustrated with 113 engravings. Price, 25s. net.

THE name of Granger in x-ray examinations of the nasal sinuses is one to be conjured with, and this little work is the outcome of the research work which he has brought to a successful conclusion in this field of x-ray investigation.

The book is essentially a collection of articles which he has written on the subject illustrated by reproductions of his private exhibits of radiographs at the Charity Hospital of Louisiana. They include experimental and comparative studies of the sinuses which are of the utmost interest and value to radiologists all over the world.

The reproductions of radiograms are on the whole clear and show with sufficient distinctness the radiological appearances of the pathological conditions involved. If one were to make a criticism, it is to be noted that the pictures have been produced without the aid of a grid, which as we know, greatly adds to the clearness and contrast. The Potter-Bucky diaphragm of course is the best of these aids to radiography and the writer has designed apparatus whereby a Potter-Bucky grid can be readily used in any of the desired positions. A fixed grid of the Lissom-type could of course be fitted to any of the apparatus described. The absence of grid technique has undoubtedly affected the clearness of the reproductions; but the value of the angular positions described remains firmly established.

We have nothing but praise for the general get up of the volume. It is worthy of the best traditions of such a distinguished firm of publishers.

J. S. S.

THE LEGAL AND ETHICAL ASPECTS OF MEDICAL QUACKERY.—By L. M. Minty, Ph.D., B.Sc., B.Com., LL.B. London: William Heinemann (Medical Books), Ltd., 1932. Pp. xviii plus 262. Price, 7s. 6d.

THE writer of this book is not a medical man; the book has suffered a little on this account. On the other hand it could not have been written by a medical man, unless he had had a vast amount of legal experience. The ideal book would be a collaboration between a medical man and a lawyer; the author of this book sought a medical collaborator but he was advised that the General Medical Council would be likely to disapprove. On the whole we feel that, if the addition of a medical collaborator would have affected the freedom of the discussion, it is after all as well that this collaboration was not brought about. There are many difficulties in the way of achieving the ideal.

The title of the book might well have been abbreviated, as it is almost entirely the legal aspects of medical quackery that are discussed. The author starts by giving a definition of the word 'Quack'. The exact meaning of the word has a very important legal significance and in one case a reversal of a £1,000 judgement was obtained because the judge had told the jury that to call a man a 'quack' meant that he was unqualified; its actual meaning is 'one who adopts the practices of a person who has no medical skill but induces patients to come to him by advertisement, self-praise and the abuse of others'. There are unfortunately qualified medical men who do adopt these methods, but it will be seen from this book that it is a very dangerous thing to call any man a quack in public, and though you may be exposing an arrant rogue and doing a signal service to your fellows, it will cost you a small fortune in legal fees, even if you do eventually obtain judgement in your own favour.

In the section on infamous conduct in a professional sense, the author shows himself prejudiced. It is in some ways a pity that he did not confine himself to citing cases on which he was not personally involved. He could then have given a less prejudiced criticism of the General Medical Council. He complains that the Act of 1858 gave the General Medical Council powers which the legislature never meant them to have. It strikes us as rather amusing that the medical profession should have beaten the legal profession on the latter's own ground. He considers that a new medical Act is necessary to make the General Medical Council treat all, famous surgeons and poor practitioners, alike. This accusation of favouring the rich is again a little unfair—the General Medical Council are notoriously lenient to knighted surgeons in their dotage, not, we are sure, because they are afraid of them but because on the whole they do little harm and would gain considerable notoriety by any legal action.

In the section on abortion the author is again, in our opinion, unjust. The injustice in this case is to this country and is born of ignorance. He implies that a considerable number of Indian students in England supplement their allowances by practising abortion. He writes, 'In India abortion is not an offence. The ordinary means used by the Dhahs or Indian professional abortifacient is to insert a twig.....'

Amongst the causes of death associated with the illegal operation of the abortifacient, he includes 'fright', *per se*, prior to the operation, not, we imagine, a common cause of death in an otherwise healthy woman.

The book is not very light reading and there is little comic relief; however, there was one sentence which amused the reviewer:—A member of the House of Lords protested violently against Lister being raised to the peerage, because a month previously for a fee of five guineas he had carried out a digital examination of this noble Marquis's rectum.

For the book as a whole and for the author's method of dealing with the various subjects we have nothing but praise to offer. Any medical man will find much that he

can apply in his own experience and he may find guidance for the future. To those who have a special interest in the legal aspect of medical practice the book will be very valuable indeed.

L. E. N.

A TEXTBOOK OF PATHOLOGY: AN INTRODUCTION TO MEDICINE.—By W. Boyd, M.D., F.R.C.P. (Ed.), F.R.C.P. (Lond.), Dipl. Psych., F.R.C.S., London: Henry Kimpton, 1932. Pp. 946. Illustrated with 287 engravings and coloured plates. Price, 45s.

As the author of this excellent book points out in his preface, in the matter of writing books on pathology it is not possible to serve two masters. A decision has to be made and in this case the author has decided—no doubt with the urging of the publishers—in favour of maummon, and has written this book for the benefit of the student, but his definition of the student is a comprehensive one, and his motto is apparently 'aren't we all'. The Gods he refers to such books as the fourteen-volume system of Henke and Lubarsch.

The author seems to regret that the student has to commence his studies in pathology before he has had any clinical experience and that he is therefore often unable to appreciate the significance of the pathological changes he is shown. To get over this difficulty the author has included a very short account of the etiology and clinical picture in many instances and in others he has given a valuable paragraph on the correlation of the signs and symptoms of the disease and the morbid changes as observed in the pathological laboratory. (We might mention, parenthetically, that clinical teachers complain that, when they commence their practical work, students have not sufficient grounding in pathology to enable them to appreciate the significance of clinical signs and symptoms. The only way to please both would be for a student, after having passed his final examination in all subjects, to go back to the beginning and take his whole course again; this is unfortunately not practicable in our temporal world.) The author has also realized the importance of the application of physiology and has in every case given a short résumé of the important physiological functions of the various organs.

The book is divided into the usual two sections, general and special. It is surprising what an enormous field has to be covered by a book of this nature and how little space can be given to each subject. The author has, however, made the best use of this space and has not 'sacrificed the student to satisfy his own sense of completeness'. This last sentence is paraphrased from the author's preface, but the words are almost those we used recently about another book, without the negative.

The author's style and method of presentation of the subject make the book easy and pleasant to read, but he introduces now and then remarks which the student might accept as aphorisms, and which do not deserve this appellation as they frequently require both amplification and modification. For example, while discussing hepato-splenic fibrosis, he writes 'when the liver is principally affected the condition is called cirrhosis. When the main lesions are in the spleen the condition is called splenic anæmia'. He also uses modern expressions which are occasionally so apt that even the most pedantic reader will forgive him, but the forgiveness is dependent on the aptitude, which is not always evident; reference to red blood cells being 'parked' in the spleen to meet an emergency cannot be forgiven on these grounds. The offending word comes in a paragraph commencing '*The bank function*' (of the spleen). Why exchange a good metaphor for a bad one?

These are, of course, quibbles which do not detract from the solid value of the book. We strongly recommend it both to the young student and to the practitioner.

L. E. N.

A NEW DICTIONARY FOR NURSES.—Compiled by Lois Oakes, S.R.N., D.N. (Lond. and Leeds). Edinburgh: E. & S. Livingstone, 1932. Pp. xvii plus 345. Illustrated. Price, Rs. 2-4. Obtainable from Messrs. Butterworth and Co. (India), Ltd., Calcutta.

There are possibly other dictionaries of this kind on the market but we have not seen them. The medical dictionary is too bulky and too expensive for the ordinary nurse, and in standard dictionaries many words in common use in the ward and operating theatre will not be found.

Despite the fact that much has been compressed into a very small space, the compiler of this dictionary has not been content to give the meaning of words alone, but has added notes which will be useful to a nurse; for example under 'avertin', in a column and a half the author has given most of the details necessary for making avertin solution, for preparing the patient, and for the administration of this drug.

A few pages are devoted to useful information on such subjects as abbreviations, comparative temperature scales, and weights and measures. There is an appendix which also contains useful information—e.g., a synonymy of diseases, dietary tables and calorific values—and a table of historical medical facts, which seems somewhat out of place in a book of this utility.

The book is well-printed and neatly bound, and is entirely suitable for the purpose for which it was compiled.

Annual Reports

REPORT ON THE SESSION OF THE OFFICE INTERNATIONAL D'HYGIENE PUBLIQUE, HELD IN PARIS FROM 25TH APRIL TO 4TH MAY, 1932. BY MAJOR-GENERAL J. W. D. MEGAW, C.I.E., K.R.P., I.M.S., DELEGATE FOR THE GOVERNMENT OF INDIA. SIMLA: GOVERNMENT OF INDIA PRESS.

The Office International d'Hygiène Publique is the headquarters and representative body of the signatory nations to the International Sanitary Convention. It holds meetings twice a year, and issues a monthly bulletin. Its proceedings and publications are in French and therefore may not obtain the publicity in India which their importance deserves. General Megaw's interesting summary deals with the spring meeting at which several matters were dealt with of extreme interest and importance to India. Perhaps the most important

is the question of the new Aerial Traffic Convention, and that part of it which particularly refers to the powers proposed to be granted to countries that have reasons to fear the introduction of yellow fever into their territories. India is in this position and should either the virus or a case of yellow fever be brought to India, the possibilities would be disastrous. The former contingency has been dealt with by legal powers, but the second remains a very real possibility. The convention previously proposed and agreed to by the 'Office' placed reliance on vigorous action at the ports of departure of the yellow fever country and at the ports of arrival of the defending country. The Government of India did not consider that these provisions afforded adequate protection and General Megaw was able to ensure such modification of the convention that the Government of India would have the right to refuse

or prohibit the landing of aeroplanes from yellow fever countries, if it thought it necessary to do so. When one considers the ease with which the yellow fever virus can be passed on to man even without the intervention of the mosquito, and the proved fact that the stegomyia can be transported easily by aeroplanes, the wisdom of such a provision of protection to India is manifest, and General Megaw is to be congratulated on the tactful manner in which he successfully removed misunderstandings and attained his object.

A great deal of attention was given to plague and its prevention by inoculation. Considerable doubt has recently been cast on the value of prophylaxis of plague by inoculation, especially by Italian and Dutch delegates. A report from India by Naidu and Taylor received close consideration and apparently convinced most of the assembly that prophylaxis by plague-vaccine, as prepared in the Haffkine Institute by carefully controlled methods at every stage, was a demonstrated fact, and that the Haffkine method of preparation by growth in broth was superior to the method by growth on a solid medium. Independent observation by Professor Ledingham appears to corroborate this statement. The new serum therapy of plague as reported by Naidu and Mackie also attracted attention. Reference is also made to important contributions by Williams and others on methods of rat destruction. These papers are published in the monthly Bulletin which should be consulted. Rat destruction and rat proofing of houses and ships are now recognised as measures of the first importance in preventing the carriage and propagation of human plague.

There are some interesting observations on smallpox and vaccination. Dried vaccine lymph has been exclusively used in French Equatorial Africa since 1924. It is apparently more easily transported than glycerinated lymph. Three cases of encephalitis following anti-typhoid inoculation were reported and a protozoon related to *Encephalitozoon cuniculi* of the hare has been reported to have been found by Dr. Kling in the neuraxons of two cases of post-vaccinal encephalitis.

Tuberculosis was also a subject of debate and an interesting note is given of a visit paid to Dr. Calmette's laboratory in the Pasteur Institute of Paris. Dr. Wefring of Norway holds that a negative von Pirquet reaction in nurses and others, who have to look after cases of tuberculosis, is a sign of dangerous susceptibility and that such persons should be inoculated subcutaneously with B. C. G. so as to give a positive von Pirquet, which would then denote a degree of protection. English public-health and tuberculosis workers have been accused of a want of enthusiasm in not experimenting with the B. C. G., but Sir G. Buchanan explained that the method of administration of B. C. G. to newly born infants, which also necessitates the removal of infants from infectious surroundings for a period of 4 weeks, would be impracticable in England and also unnecessary, since the measures in England have reduced the mortality amongst infants of under 1 year from 1,311 in 1921 to 585 in 1930. He admits that subcutaneous inoculation of B. C. G. would have an application in creating temporary immunity among persons who are not already immune, for example nurses working in tuberculosis hospitals or persons coming to towns from isolated rural areas.

The prevention of measles by immune serum, cerebro-spinal meningitis and psittacosis, relapsing fever, and the 'Bornholm' disease (acute epidemic myositis) which resembles dengue, were also discussed. The bacteriology of cholera is the subject of a short note in which the characteristics of the El Tor vibrio and the transformation of the agglutinable vibrio by bacteriophage into a non-agglutinable vibrio are discussed.

It will thus be seen that the subjects discussed in the Office are always of practical importance and General Megaw is to be thanked for his very interesting résumé of the April-May meeting. (We note that

extracts from the Bulletin of the Office are now being translated in the *Bulletin of Hygiene*.)

REPORT OF THE HEALTH OFFICER OF CALCUTTA FOR 1930. BY T. N. MAJUMDAR, D.P.H., D.T.M., F.C.S. (LOND.), F.R.S. (EDIN.). CALCUTTA: PRINTED AT THE CORPORATION PRESS. 1932.

It is a pity that the Health Officer of Calcutta Corporation has not been able to catch up the arrears of his annual reports. The year 1930 is a long time ago and some more up-to-date and timely information on Calcutta would be welcome. The report follows the usual lines and there is not much of novelty to record. Nevertheless the report is interesting. The 1921 population of 1,077,264 was still being used for purposes of calculation. The birth rate was 21.9 per 1,000, the death rate 28.9 per 1,000 and the infantile mortality 262 per 1,000 live births. Cholera caused 1,755 deaths (1.6 per 1,000), smallpox 1,818 deaths (1.7 per 1,000), tuberculosis 2,756 (2.5 per 1,000), deaths from malaria were reported to be 714 (0.66 per 1,000), typhoid fever deaths were 727 (0.67 per 1,000); kala-azar accounted for 315 deaths (0.29 per 1,000) and there were no deaths from plague. The features of the report are the comparatively low birth rate, the high infantile mortality, the high mortality from tuberculosis, and the comparatively high incidence of cholera and smallpox. Mortality from tuberculosis and cholera is a measure of the primary environmental conditions of housing, drinking-water and excretal disposal, and the evidence points to these matters being extremely defective in Calcutta. There seems to be no concerted policy in Calcutta in the matter of improving proper water-borne latrines and of providing an adequate supply of filtered water in the places where it is more urgently required. The Calcutta Improvement Trust is tackling the housing problem in a certain way, though only a fringe of it can be thus touched.

There are several interesting charts showing the seasonal variations in general mortality and in the mortality from cholera, tuberculosis, smallpox and fevers. There has been a reduction of recorded mortality due to malaria since 1922, but the present report does not touch on the recent happenings as regards malaria in the city. The report describes the work of the sanitary staff throughout the year and details the medical and maternity relief afforded through dispensaries and maternity homes.

The chapter giving the work of the Corporation laboratory contains some interesting reports of investigations on water and food analysis and there are also notes on algae in Calcutta water by Dr. Banerjee, Dr. Biswas and Dr. T. K. Ghosh which are worth reading. It is suggested that a sheet of copper should be placed in the front and sides of the weir at the 'thermocline' layer. So far as we know this has not been tried. Mr. Banerjee states that the modern 'catadyn' process was known to the ancient Indians as endorsed in the Smritis and the Puranas. The investigation of the algal problem in the complete manner suggested by Mr. Biswas would be valuable—we hope to see in the reports for 1931 and 1932 that some definite methods of inquiry have been started.

ANNUAL REPORT OF THE EXECUTIVE HEALTH OFFICER FOR BOMBAY FOR THE YEAR 1931. BOMBAY: THE TIMES OF INDIA PRESS, 1932.

The population of the city of Bombay at the census of 1931 was 1,161,383, which is a reduction of 14,531, or 1.23 per cent. during the decade of 1921–30, as compared with an increase of 20 per cent. during the decennium 1911–20. The reduction was really due to depression of trade conditions during the census-taking period and cannot be taken as a real average representation of the population changes during the last decade.

In vital statistics the noteworthy feature was the fact that for the first time since 1866, the number of births in the city was higher than the number of deaths.

The birth rate for 1931 was 23.4 per 1,000, and the crude death rate 21.6 per 1,000. The chief epidemic diseases, cholera, plague and smallpox, contributed only 80, 24, and 31 deaths respectively—not a large number.

Respiratory diseases are the chief cause of mortality, diseases of infancy coming next. Malaria along with ague and remittent fever take the third place (if 'old age' be excepted), while tuberculosis comes next.

Environmental conditions.—The water supply comes from Lake Tansa and is plentiful. It is not filtered but chlorinated.

Excretal disposal has several unsatisfactory features which require immediate improvement. The sewage outfall problem seems still to be undecided but no indication of the present stage of the discussion is given. Until this outfall question has been decided, urgent work on the sewage extension cannot be commenced. There are still over 13,000 basket privies causing terribly unsanitary conditions. The conversion of these proceeds gradually but is held up on account of the absence or insufficient capacity of the sewerage system in many localities.

Defective and insufficient housing of the working classes is still a feature of Bombay and no doubt accounts for the very high mortality from respiratory diseases. The City Improvement Trust has since 1898 provided 48,987 new tenements as against 33,535 tenements demolished. Financial considerations however are stated to have led to delay in taking action in a number of the areas which have been marked down as requiring attention.

In the matter of the protection of maternal and infant life, in the provision of accommodation of infectious diseases, and for the treatment of venereal disease and in the campaign against tuberculosis, Bombay seems to be far ahead of any other Indian city.

There are now 5 municipal maternity homes, in which 3,346 women were confined during 1931. Out of 29,336 births, 18,237 or 62 per cent. took place either in maternity or municipal and other hospitals. Puerperal sepsis accounted for 93 maternal deaths out of 198.

The infantile mortality rate was 272, being the lowest figure ever recorded in the city. Maternal benefits are now extended to women of the labouring classes. Municipal nurses and welfare centres provide means of educating and helping and advising mothers, and the Infant Welfare Society has 7 centres, two maternity homes and a crèche. No mention is made of voluntary welfare work in the city mills.

The chapter on malaria is interesting in view of Major Covell's *Report on Bombay Malaria* in 1928 and his *Report on Malaria in Calcutta* in 1931. Every endeavour is apparently being made to carry out Covell's recommendations with regard to the closure and protection of wells, cisterns, tanks and mill-ponds, etc. 131 deaths were registered from malaria but 1,398 deaths as due to ague and remittent fever. The last no doubt contains many deaths due to various non-malarious fevers. Inspectors still report a large amount of anopheline breeding, though the spleen rate in the districts reported as high by Covell appear to be coming down. There is a definite objection on the part of religious bodies to whole-hearted attempts to close wells and compromises have had to be effected. Spleen rates of between 12 and 20 are common still in the municipal schools. The summary of work done in 1931 in inspections and oiling, and mosquito proofing is impressive.

The impression one gets from reading the report is that the Health Officer and his staff are active, energetic and alive to the routine and special needs of the city. The primary matters of sewage disposal and housing seem to be hanging fire and should now be dealt with definitely and vigorously.

SIXTY-FOURTH ANNUAL REPORT OF THE DIRECTOR OF PUBLIC HEALTH OF THE UNITED PROVINCES OF AGRA AND OUDH FOR THE YEAR 1931. ALLAHABAD: THE SUPERINTENDENT, PRINTING AND STATIONERY, UNITED PROVINCES, 1932. PRICE, RS. 3.

Owing to financial conditions, no maps or diagrams are included in this year's report and the size of the report has been reduced by one-third. The essential statistical information and descriptive matter however have been retained and the report as usual is interesting reading. We understood that Colonel Dunn's tenure of the appointment as Director of Public Health comes to an end this year and those who have watched the progress of public health in the U. P. know how much advance has been made in the last 15 years, and that this has been due in very great measure to Colonel Dunn's energy, perspicacity, and imagination, and no less to his eloquence and persuasive powers.

The population of the U. P. in the decade 1921—31 increased from 45,375,787 to 48,408,763. An interesting table gives the birth and death rates of 1931 for the provinces of India and the rates of natural increase. Bengal has the lowest natural rate of increase 5.57 per 1,000, the Punjab's rate for 1931 being 16.75; that of the U. P. was 8.63.

The birth rate of the U. P. for 1931 was 35.6 and the death rate 26.97 per 1,000 and the infantile death rate per 1,000 births, 179.07. The figures of mortality for various diseases showed in general a decrease as compared with 1931. *Cholera* accounted for 31,118 deaths, *plague* for 31,225 deaths and *smallpox* for 3,385. *Fevers* claimed 1,075,281 deaths, a very high figure, of which 932,796 are attributed to malaria. This is a very high figure, but the records are stated not to be very reliable.

Tuberculosis gave a general death rate in towns of 1.34 and 1.85 in the larger towns. Under *respiratory diseases* were returned 36,612 deaths.

The elementary sanitation of the towns of the province does not seem to be of a very high standard and the fly and mosquito nuisances are widespread. Municipalities seem to be averse to act on the sanitary advice tendered, or on the lines laid down in the Municipal Manual. In the rural districts, the extension of the district health staff has been postponed for lack of funds. A good deal of work has been done in village uplift and rural reconstruction by committees. The Junior Red Cross work has caught on and would appear to be doing excellent service in the schools.

The special malaria branch continued its activities in various parts of the province. Perhaps the most interesting line of work is the attempt made to control malaria by the distribution of quinine and plasmochin; 20 grains of quinine and 1/6 grain of plasmochin are given for 3 days. The results are reported to be much better than with quinine alone. Similar treatment (21 grains of quinine and 1/2 grain of plasmochin daily for 3 days) were given in some of the jails. The relapse rate is reported to be much less than with quinine treatment and much less expensive.

Plague deaths were more numerous than in 1930; inoculation and rat destruction are the methods of choice while evacuation is also used in some districts.

Maternity and child welfare is run by the Lady Chelmsford League and Indian Red Cross Society. There are now 52 centres in towns and 72 in rural areas compared with 49 and 47 in 1930. The activities nevertheless were hampered by loss of funds due to financial depression.

The public analyst reports that the work of the Food Adulteration Act is hampered by the inadequate fines administered by magistrates in food adulteration cases, and by the shortage of staff under his control. School

appointed as officiating Assistant Director, Central Research Institute, Kasauli, with effect from 17th December, 1932, or the date on which he assumes charge of his duties.

Subject to His Majesty's approval, the undermentioned officers whose appointment on probation was notified in the London Gazettes dated 12th and 19th February, 1932, are confirmed in the following order on passing the necessary courses of instruction:—

Captains

R. A. Wesson; W. Happer; J. J. Quinlan.

Lieutenants

R. J. Jarvie; W. A. N. Marrow; F. A. B. Sheppard; M. Sendak; R. I. Reid; F. C. Jackson.

LEAVE

Lieutenant-Colonel R. Knowles, Professor of Protozoology, School of Tropical Medicine, Calcutta, is allowed leave for 2 months and 25 days, in extension of the leave granted to him in the previous notification.

Lieutenant-Colonel E. H. V. Hodge, Civil Surgeon, Howrah, is granted leave on average pay for 6 months, with effect from the 17th November, 1932. This cancels previous notification.

PROMOTIONS

Lieutenant to be Captain (provl.)

D. J. Young. Dated 30th September, 1932.

Lieutenant (on prob.) to be Captain (provl.) (on prob.)

B. L. Taneja. Dated 19th November, 1932.

The seniority of Lieutenant (on prob.) J. D. Grant is antedated to 20th April, 1931.

RESIGNATION

The Governor-General is pleased to accept the resignation by the Honourable Major-General J. W. D. Megaw, C.I.E., K.H.F., of his office of Member of the Council of State.

RETIREMENT

Lieutenant-Colonel R. H. Bott, C.I.E., retires 10th November, 1932.

Notes

SPECIAL TONGUE FORCEPS

By J. B. BLAIKLEY, F.R.C.S.

THE small tongue forceps illustrated have been made for me by Messrs. Down Bros., Ltd., for use in the resuscitation of new-born infants.

The chief advantage claimed for this instrument is that once the tongue is pulled forward the forceps holds it there by its own weight.

Corbould introduced self-retaining tongue forceps, but not of a suitably light pattern necessary when applied to an infant. The use of these forceps ensures a clear airway once all mucus is aspirated, while dispensing with an extra hand necessary to hold the forceps; this is particularly of value when carbon dioxide is being administered from a sparklet apparatus by means of a rubber face mask, which fits neatly over the proximal portion of the forceps.

In artificial respiration of an infant the operator is not embarrassed by a second person's hand over the chest holding the tongue forwards.

FOCAL INFECTIONS

UNDER the above title the British Hanovia Quartz Lamp Co., Slough, England, have issued a little booklet dealing with the use of actinotherapy in focal infections. These embrace such widespread and different conditions as diseases of the throat, nose and ear, adenitis

and tonsillitis, the use of ultra-violet rays to abort a cold, sinusitis, furunculosis, erysipelas, ringworm, the healing of wounds, etc.

The booklet can be obtained free by any Indian medical practitioner on application to the following agents:—

Messrs. Malgham Bros., 26, Custom House Road, Fort, Bombay.

Messrs. L. G. Vimar, Bijli House, 38, New Theatre Road, Calcutta.

Messrs. Adair, Dutt & Co., Keleeli Mansions, Mount Road, Madras.

SCHERING-KAHLBAUM, A.G., BERLIN

THE well-known continental firm of manufacturing chemists, Schering-Kahlbaum, have recently celebrated their 60th anniversary. In 1927, the firm of Kahlbaum was merged with that of the original concern, E. Schering, which was founded in 1861. They have recently issued an attractive booklet in which there is a short history of the gradual evolution of modern pharmacy from the times of the Chaldaic magicians, through periods of alchemism and sorcery, to the present-day period of carefully-standardised natural and synthetic medical preparations. The subject is an epic one and must appeal to all interested in human progress.

The manufacturing chemist of to-day is not content merely to place on the market a pure and standardised form of the pharmacopœial drugs, but employs an army of chemists and pharmacologists who are continually experimenting with new preparations. The Schering-Kahlbaum list of their original preparations is far too long to quote here and most readers will be familiar with them; amongst the most outstanding are urotropin, neotropin, veramon and atophan, names so familiar to the physician of to-day that he scarcely realises that they are proprietary drugs.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

NOTES ON MAKING EPIDEMIC FORECASTS

By SIR LEONARD ROGERS, K.C.S.I., M.D., F.R.C.P., F.R.S.
MAJOR-GENERAL, I.M.S. (ret'd.)

At the beginning of each of the last three years and again this year I have submitted forecasts of the probable incidence during the succeeding year of India's three most important epidemic diseases, cholera, smallpox and plague. Each forecast has proved to be very accurate. These forecasts were the outcome of a study of the relationship between certain climatic occurrences and the incidence of these diseases during the last sixty years, and were based on climatic data sent from India to me in London.

As I shall not much longer have ready access to the necessary data I propose to give in this paper the information required to enable the forecasts to be worked out in India itself by Public Health Commissioners or others who may possibly be sufficiently interested in the subject to test for themselves, at the cost of a few minutes a month, if my methods have any value or not. For this purpose I have given in a table the necessary climatic data, which can be filled in each month from the data published in the monthly weather reports of the Director-General of Observatories, Poona. In my own tables I enter the climatic data favouring increased prevalence of cholera and smallpox in bold type, and those indicating low prevalence in green ink; this allows the general tendency of the data to be seen at a glance. In the table the variations from the normal, of sufficient degree to be likely to influence subsequent increases or decreases of the prevalence of the three epidemic diseases dealt with, are shown in larger type to allow the explanations given below to be followed readily. If anyone in India is willing to test my methods I shall be glad to give him any further information in my power that he may require.

The climatic data used in forecasting and methods of obtaining them

In my first forecast, which appeared in the *Indian Medical Gazette* of March 1930, I summarised the climatic data on which the forecasts in my former papers are based, and I now illustrate them by the data (*vide* table) of two years in the Punjab, selected to show the climatic factors related to increased and decreased incidence, respectively, of cholera, smallpox and plague. The monthly variations from the average figures of a number of years are given for (1) the mean monthly temperature, (2) the mean 8-hours monthly relative humidity, (3) the mean vapour tension, or absolute humidity, at 8 hours, (4) the mean

monthly saturation deficiency calculated from (1) and (3), and (5) the monthly rainfall in inches. In my own tables the actual monthly data are also inserted, but are omitted from the table here for simplicity's sake. Below the data of each year are shown the monthly death rates per 100,000, the annual total deaths and the death rates per mille for cholera, smallpox and plague, respectively, for the *following year*. These are worked out from the numbers recorded in the annual provincial sanitary reports, and in preparing tables of them for several decades I found it saved much time if tables were first made of the rates per 100,000 from 0.1 to 10.0 with the aid of the millions of inhabitants of each area of each decennial census, which are given in the sanitary reports, as from these the ordinary monthly rates can be seen at a glance and those over 10.0 are quickly calculated.

Sources and methods of calculating the required climatic data

The necessary data can all be obtained directly or indirectly from the monthly weather reports published a few days after the end of each month by the Director-General of Observatories, Poona, to whom I wish once more to acknowledge my great indebtedness for supplying me with absolute humidity figures for several decades and many other data. In my studies of over half a century past I used the monthly temperature and rainfall records of a central station in each province, taken from the records still published in annual reports of the Sanitary Commissioner with the Government of India some two years after the periods to which they relate. In preparing forecasting tables the up-to-date monthly weather reports are essential, and either the figures of a central place in a province or area, or, better still, those of each province or area being dealt with, can be obtained from these reports as follows:—

(1) *The mean monthly temperatures* are obtained by adding together the mean 8-hours maximum and minimum temperatures and dividing by two. To obtain the actual figures for each province or smaller area, the mean of the highest and lowest readings of the particular data required, recorded for the various places in each area, are taken in making the estimation, but the variations from the normal maximum and minimum monthly temperatures are given both for provinces and for sub-divisions in the monthly reports, from which the monthly departures from the normal mean temperatures can be calculated and entered at once in the forecasting table under the appropriate month.

(2) *The monthly relative humidities* are also given in the same reports for a number of places in each province, the means of which will give the provincial and sub-divisional data, while the departures from the normals can be

taken directly from the first two tables of the report.

(3) *The mean vapour tension, or absolute humidities*, are not published in the monthly weather reports, but their departures from the normal are recorded in table 7 of the Indian weather review annual summary, but as these are not available until a year or so later they must be calculated for the forecasting tables from other data in the monthly weather reports; namely, the wet and dry bulb readings, the means of those of the different provinces and sub-divisions being taken when their absolute humidities are required. The wet-bulb 8-hours mean and the difference between that figure and the dry-bulb mean thus obtained will enable the absolute humidity of the nearest whole numbers to be found from nos. X and XI of 'Tables for the reduction of meteorological observations in India' published by the department in 1910, that table calculated for the nearest barometrical readings to those of the province being dealt with being selected, and the slight differences for the fractions of a degree in the wet bulb and difference from the dry bulb are easily estimated from the data in the tables mentioned.

(4) *The saturation deficiencies* can then be readily worked out by taking the figure of the saturation point of the mean temperature of the month from table IX, of the same publication, of vapour pressures and subtracting the absolute humidity figure from it. The saturation-deficiency figure thus obtained is a measure of the drying power of the air, a high figure meaning a great drying power, and *vice versa*. I found it convenient to amplify table IX with the data of each 0.1 of a degree between those given in the table for each 0.2 of a degree for the temperatures requiring to be used. Doubtless the Indian meteorological department will be glad to supply public health officers each month with any such data for their province.

(5) *The monthly rainfalls* and their departures from the normals can also be taken straight from the monthly weather reports.

The climatic factors influencing the subsequent prevalence of cholera, smallpox and plague respectively

In order to illustrate the climatic factors favourable to and adverse to increased cholera, smallpox and plague, respectively, I have selected the data of the Punjab in 1917 and 1918 on account of the unusually wide variations from the normal they showed, followed by the epidemic prevalence of the diseases dealt with, but it must be remembered that the Punjab shows the greatest variations of all the provinces of India in both climatic conditions and the prevalence of epidemics, and lesser variations of the climatic data from the normal may be of significance in forecasting.

Increased cholera prevalence in 1919 following low 1918 monsoon rains

In my table the major variations from the normal in the meteorological data which influenced subsequent disease incidence are shown in larger figures to enable the description to be followed more easily. The significance of *plus* and *minus* data on each disease is also indicated in the table. In my comprehensive study of some sixty years, monthly cholera and climatic data recorded in the *Indian Journal of Medical Research Memoirs*, No. 9 of March 1928, I showed that no less than 40 of the 41 cholera epidemics in various parts of India during a period of forty-five years, the outbreaks followed deficient rainfall in the areas affected during the previous year's monsoon, and often also in the following winter months, while the single exception was due to the Allahabad Kumbh Fair of 1894. The table illustrates such an epidemic in the Punjab in 1919 following a deficit of 8.23 inches of rain, or 42 per cent of the total, in 1918, and a deficit of 7.79 inches, or 52 per cent, in the monsoon quarter of July to September; the monthly figures for Lahore showed only 5.64 inches in those three monsoon months against a normal of 13.43. As usual cholera only broke out in the Punjab in April of the following year, when the monthly absolute humidity there first rises above 0.400 (below which point I showed in my memoir that cholera never becomes widely prevalent in any province of India) and the disease became widespread at the usual Punjab cholera season of June to September, with 8,561 deaths, or 0.44 per mille, for the year, against a five-yearly average from 1916 to 1920, including an epidemic year, of 0.12 per mille.

Low cholera following heavy monsoon rains in the previous year

The table also furnishes an example of the very high rainfall of 1917 of 36.79 inches, an excess of no less than 16.93 inches, or 85 per cent, being followed by the very low figure of 257 cholera deaths in 1918, or 0.01 per mille, one of the lowest Punjab rates on record.

Epidemic smallpox in 1919 following low monsoon and autumn absolute humidities in 1918

In my study of nearly half a century's monthly records of smallpox in the different provinces of India in relation to the climatic data (*Medical Research Council Special Report Series*, No. 106, 1926) I showed that in the seven provinces that received the full effects of the south-west monsoon the disease reaches its yearly minimum during the high absolute humidity of that season, but the incidence remains high in most of Madras which gets little of the south-west monsoon rain. Further, the worst outbreaks of smallpox occur in north-west and central India in the year following a failure of the monsoon in those areas, which are most

tion deficiency in May 1910 as usual.

closely correlated with low average monsoon and autumn absolute humidity due to short rains, as the annual monsoon decline is less, and the regular smallpox rise in November and December starts from a higher level with resulting high rates throughout the ensuing winter and hot weather seasons, until the full establishment of the next monsoon rains brings it down again. This sequence of events is well illustrated by the absolute humidity data of 1918 and the smallpox rates of 1919 in the lower half of the table, for the monsoon and absolute humidity rates from July to November were exceptionally low, and the smallpox incidence rose rapidly to well above the average for that month in December 1918 and continued above the average through 1919, with the maximum as usual in the hot season; 15,365 deaths, or 0.79 per mille, were recorded in 1919, against an average of 0.12 per mille in the previous five non-epidemic years.

Low smallpox following previous high monsoon absolute humidity

On the contrary, the very high absolute humidity from May to October 1917, accompanying the excessive rains of that year, was followed by low smallpox incidence in the first nine months of 1918, during which year 3,032 deaths were recorded, no less than 1,544 of which were in the last quarter of the year following low monsoon absolute humidity of the 1918 monsoon, against only 285 in that quarter of 1917.

High plague incidence in 1918 following low temperatures in the hot season and low saturation deficiencies in 1917

In my study of 23 years plague records in India in relation to climate (*Proceedings of the Royal Society, Series B, Vol. 103, p. 42*) I showed that low monthly mean temperatures in the hot weather and monsoon seasons, and low saturation deficiencies at all times of the year, are likely to be followed by high plague incidence. On the contrary, high hot weather temperatures and high saturation deficiencies are followed by decreased plague; doubtless owing to their unfavourable influence on the life of plague-infected rat fleas which convey the disease to man. As the latter conditions occur especially in years of low rainfall and low monsoon absolute humidity, it is clear that decreased plague is probable in years favourable to increased cholera and smallpox, as is illustrated in the table. Thus the low rainfall and absolute humidities in 1918, followed by high cholera and smallpox, were accompanied as usual by high temperatures and saturation deficiencies with consequent comparatively low plague incidence in 1919, 11,068 deaths, or 0.57 per mille, against an average for the previous five years of 4.07 per mille which included the epidemic year 1915. On the other hand, in

MALIGNANT DISEASE IN THE PUNJAB

By VISHWA NATH, M.A., M.D., F.R.C.P.I.,
D.P.H., D.T.M. & H.

RAI BAHADUR JIWAN LALL, M.D., B.S.

and

JAGAT SINGH, M.B., B.S.

*Department of Pathology, King Edward Medical College,
Lahore*

No idea of the mortality from malignant disease can be formed from the vital statistics published for India as a whole, or from the statistics of her constituent provinces. It is still more difficult to form an idea of the morbidity due to malignant disease. So far as the cancer portion of malignant disease is concerned, enthusiasts publish from time to time statistics to suit their own theories, but wherefrom and how they get their figures seldom receives consideration. For example Marwood (1926) trying to prove the association between the salt consumption of a country and its cancer mortality states the cancer death-rate for India and China to be 11.7 and 8.1 per hundred thousand and for the United Kingdom and the United States of America 121.5 and 100 per hundred thousand, respectively. His statistics for the western countries may be correct, but those regarding India and China can only be conjectural. Others base their impressions of lower incidence and mortality of cancer in India on lack of "civilization", (Vedder, 1927), peculiarities or insufficiency of diet, etc., but all such theses are mere assertions based on little or no investigation.

Vital statistics in India are not based on death certificates issued by qualified medical practitioners. Nine-tenths of the population is settled in villages; a great majority of these

(Continued from previous column)

1917 the high rainfall and absolute humidity were naturally accompanied by low mean temperatures from April to November, and low saturation deficiencies from May to October, with the result that the plague incidence did not decline as much as usual in the late hot weather and monsoon months of 1917, it rose above the average during the last quarter of that year, and reached epidemic prevalence during the usual yearly maximum season in the first five months of 1918, with 95,615 deaths in the year, or 4.94 per mille; this figure would be still higher if the figures for the twelve months from October 1917 to September 1918 are taken. The 1918 plague deaths were just ten times the average of the two preceding and four subsequent non-epidemic years, and the highest rates occurred in relation to low mean temperatures and saturation deficiencies in March and April of that year, and the rate declined with unusual rapidity in June, after exceptional high mean temperature and saturation deficiency in May 1918 as usual.

cannot and do not support a doctor of any description. The village watchman (chowkidar), poor and illiterate, is the diagnostician who reports to the nearest police station once or twice a month the deaths occurring in his area and the causes as he knows them. It is this information which is the foundation of Indian vital statistics. Even in urban areas well served by qualified medical practitioners, it has not yet proved practicable to introduce proper certification of deaths.

Crude as they are, these statistics cannot, however, be regarded as valueless for all purposes. Epidemic diseases still form the most important factor in Indian mortality and even a village watchman may be trusted to report, more or less correctly, deaths from diseases like plague and cholera when they appear in epidemic form and although headings like "respiratory diseases" and "fevers" as causes of death may fall short of western standards of vital statistics, their analysis by capable epidemiologists has yielded data which not only form valuable contributions to epidemiology, but have even encouraged philosophical speculation in search of a unity of mechanism behind different epidemic diseases (Gill, 1928).

In the assessment of cancer mortality, however, these statistics are not only no help, but a definite hindrance. With epidemic and non-epidemic infectious diseases so common in the country, not many cancer patients—with their vitality diminished—can escape death from prevailing infections, which are then naturally recorded as the cause of death. The anaemia, emaciation and cachexia, obvious enough for a village chowkidar to see, are also and more commonly features of chronic infectious and parasitic diseases in India, and these mask cancer mortality not only in rural but also in urban areas. Few of the practitioners of the indigenous systems of medicine, whose contact with the Indian public is undoubtedly more intimate, will recognise cancer. The staff of charitable hospitals apart, the clientèle of the medical practitioner, trained in western scientific medicine, is drawn mainly from the comparatively literate section of the population. Some knowledge regarding cancer, therefore, does exist in this section of the lay public. The great mass of the unlettered population, however, is not aware of cancer as a disease in the way that it is of plague, cholera, dysentery, malaria, etc.

The literature published from India on malignant disease is meagre. Neve (1902) published a paper on a "Decade of tumour surgery in Kashmere Mission Hospital", in which he brought out the importance of long-continued irritation caused by kangri burns in the aetiology of kangri cancer. Sutherland (1904) published a paper on "Statistics of malignant disease admitted to the Mayo Hospital, Lahore, from 1892-1903", in which he showed that of 43,412 cases admitted to the

hospital during those twelve years, 792 were cases of malignant disease, which he classified as follows:—"Carcinoma 400, sarcoma 334, abdominal growths 35, and malignant growths 23".

Amongst the cancer cases 58 were epitheliomas and 36 rodent ulcers. He attributed scalp cancers amongst Mohammedans to the irritation from blunt razors used in shaving their heads. Amongst recent contributions dealing with cancer in India are two papers concerned with the examination of material from Pathology museums in Madras (Basu and Vasudevan, 1929) and Bombay (Gharpure, 1927) medical colleges, and Sir Leonard Rogers' Lettsonian Lectures in 1925, giving an analysis of 1,190 cases examined in Calcutta, 579 of which were malignant and 421 non-malignant. Certain annual reports also occasionally bring out facts regarding prevalence of malignant disease. For instance the "Annual report and statistics, Government General Hospital, Madras, for 1927" showed that 13,158 patients were admitted to the hospital that year. Six thousand three hundred and forty-six out of this number were admitted to the surgical ward and of these 258 suffered from malignant disease—177 from cancer and 24 from sarcomas.

Megaw and Gupta (1927) issued a questionnaire to all civil surgeons in medical charge of districts in India. This was an attempt, not to obtain statistical information which would have failed, but just to know whether particular diseases were "common", "rare" or "unknown" in different districts. Information obtained regarding distribution of cancer through this questionnaire was valuable, although replies of some of the medical officers who returned certain types of cancer as "unknown" in their districts must either have been casual or their opportunities of seeing patients limited. Information was called for in respect of cancer of the breast, uterus, stomach, mouth and skin. From the Punjab 21 medical officers answered the questionnaire and of these as many as eight affirmed that cancer of the skin was "unknown" in their districts—a statement very difficult to believe. On the other hand the statement that cancer of the stomach was "unknown" in as many as 15 districts, "rare" in six and "common" in none is not incredible, knowing as we do how rarely do surgeons and pathologists meet with this lesion in the Punjab.

In western countries the view is expressed that so far as cancer mortality is concerned, it will not attain a desired standard of accuracy until a very much larger proportion of vital statistics depends on autopsy findings than is the case at present (Gideon Wells, 1923). Error in diagnosis in internal tumours is said to be as high as 37.1 per cent. in the United States of America and 37.3 per cent. in England.

In 1902 Reichelmann showed in Berlin by an analysis of 7,790 autopsy records that of

cases diagnosed "cancer" at autopsy 22 per cent. had not been recognised as suffering from that disease during life (Vedder, 1927).

Table I gives an idea of comparative incidence of cancer found on post-mortem examination in certain non-European countries :—

TABLE I

Number		Punjab	Porto Rico	Haiti (Choisser, 1930)	Java (Sitsen, 1928)	Philippines, Manila (Vedder, 1927)
1	Total number of autopsies ..	329	120	700	3,025	8,960
2	Number of autopsies in which malignant disease found.	14	7	27	75	233
3	No. 2 expressed as a percentage of No. 1.	4.25	5.83	3.43	2.5	2.6

In India not only are the basic records on which vital statistics based poor, but any better view which could be obtained of the causation of death, through post-mortem examinations, is also unattainable. So great is the prejudice on the part of relations to submitting the dead to a post-mortem examination, that post-mortem pathological investigation is possible only on stray unclaimed bodies.

The institution from which this paper is issued is part of the biggest teaching hospital in the Punjab and yet between 1921 and 1931 (both years included) only 329 post-mortems were carried out for pathological investigation. Malignant disease was diagnosed in 14 cases in this series. Of these 14 ten were carcinomas, one lymphosarcoma, two other sarcomas and one pulmonary growth secondary to a teratoma testis.

The distribution according to organs was as follows :—

Carcinoma	Sarcoma	Teratoma
Liver 1	Rib 1	Testis with
Stomach 2	Generalised 1	metastases in
Esophagus 1	Lymphosarcoma 1	lung 1
Pancreas 1		
Lung (Primary bronchogenic) 1		
Bladder 3		
Kidney 1		

These statistics, although too meagre to warrant any generalizations, nevertheless go to show that malignant disease is not an unimportant factor in mortality amongst people of non-European descent.

Some idea of the incidence of cancer amongst these people may also be obtained from statistics of biopsy examinations. Analysis of some Indian material by Sir Leonard Rogers has already been referred to. The following statistics of biopsy examinations carried out in the pathological department of the King Edward Medical College, Lahore, are given to afford some idea of the extent to which malignant disease contributed to the material examined.

Total number of specimens examined histologically from 1922 to 1931	3,850
Non-neoplastic	2,309
Neoplastic	1,541
Innocent new growths ..	649
Malignant new growths ..	892
Carcinomata	634
Sarcomata	211
Other malignant neoplasms ..	47

A statement comparing the above statistics with those available from some other non-European countries is given below (table II) :—

TABLE II

Number		Punjab	ANNAM HOSPITALS			Java (Sitsen, 1928)	Mexico (Maxwell, 1928)
			Saigon (Bablet, 1926)	Cholon (Bablet, 1926)	Tonking (Bablet, 1932)		
1	Total number of new growths examined.	1,541	357	650	..	1,240	..
2	Number of malignant new growths examined.	892	128	178	784	629	1,133
3	Malignant growths expressed as a percentage of total number of new growths.	57.88	35.86	27.4	..	50.7	..
4	Proportion of carcinoma to sarcoma.	3 : 1	3.5 : 1	4 : 1	6.58 : 1	2.15 : 1	3.3 : 1

Table III gives the distribution of cancer and sarcoma according to sex, age and community. Many specimens come for examination without any particulars being furnished as to age, sex, community or clinical history. Of 845 cases, diagnosed cancer or sarcoma, information as to sex was available in 692 and as to sex, age and community in 536.

This table (III) shows that the incidence of cancer in the two sexes is about equal. The preponderance of breast and uterine cancers in the female is balanced by heavier incidence of skin, lip and tongue cancer in the male. Of 29 specimens of rodent ulcer examined, information as to patients' sex was wanting in three. Of the remaining 26, 23 specimens came from male cases and only 3 from females. The age group with the highest incidence of cancer is

and outpatients' departments from 1923 to 1931. Out of this number histological confirmation of the clinical diagnosis was obtained in 523 cases. The opportunities for utilising the services of the pathology department of the college are exceptional so far as the Mayo Hospital is concerned, although the mofussil hospitals also use it in degree varying with the enthusiasm of the medical officers in charge. The proportion, therefore, of histologically-verified cases of malignancy to the total number of cases clinically diagnosed, i.e., 1:5, may be of interest when studying the figures of malignant disease as furnished by Government hospitals from all over the province. Table (V) compiled from the reports of the Inspector-General of Civil Hospitals, Punjab, from 1923 to 1931 gives the number of cases of malignant disease

TABLE IV

	Punjab	Manila (Vedder, 1927)	China	Mexico (Maxwell, 1928)	Porto Rico	Annam (Bablet, 1926)	Egypt (Dolbey and Moore, 1924)
Breast (per cent.) ..	14.8	11.15	18	18.19	10	8.3	11
Uterus and cervix (per cent.)	8.85	6.86	12	12.36	12.24	11	3.66
Penis (per cent.) ..	4.14	5.15	..	14.04	13	10	..

from 41 to 50 for both sexes. The highest incidence, therefore, occurs about a decade earlier than in Europe and North America. Over 90 per cent. of cases fall within the age group 21 to 60.

The above is not the case with sarcomas, in which the age period with highest incidence appears to be 21 to 30. The proportion between male and female incidence was about 2 to 1.

The comparative table (IV) may also prove of interest. The incidence in the organs considered is a percentage of the total number of specimens of malignant disease examined.

As regards incidence in different organs the following facts may be of interest in the Punjab statistics:—

The heaviest incidence of malignancy is on the breast 14.8 per cent. Skin cancers including rodent ulcer and cancer of the tongue constitute about 13 per cent. of the total. Female reproductive organs come next. Malignant growths of the liver and digestive tract together account for 4.8 per cent. The penis comes next with 4.14 per cent. Of 93 senile prostates examined 16 were cancerous. Nine tumours of the thyroid were found to be malignant. Of benign tumours uterine fibroid accounted for 8 per cent.

In the Mayo Hospital, Lahore, which is attached for teaching purposes to the King Edward Medical College, Lahore, 2,775 cases of malignant disease were treated in the wards

treated in the Government hospitals of each district of the province. It also gives the number of deaths from malignant disease which took place in the Government hospitals of each district. This mortality must not be taken, however, as representing either the total fatalities from this cause or the percentage of inoperable cases which come for relief to these hospitals. If it represents anything at all, it represents mortality under operation and the very small margin of accommodation available in State hospitals for incurable and moribund cases.

Another table giving similar information from the Mayo Hospital, Lahore, is also given. It tabulates separately cases of malignant disease treated in the outdoor and indoor departments of the hospital. As a background to these statistics of malignant disease the total number of indoor and outdoor patients treated each year is also given.

In the table for the whole province (table V), it will be noticed that the highest figures for malignant disease obtain in the districts of Ludhiana, Ferozepur, Lahore and Amritsar. Hissar also shows a higher level than many other districts. The excess in the districts mentioned cannot be taken to mean a higher incidence of malignant disease in those localities, but only the presence of better hospital and laboratory aid, so that patients are attracted to these centres from other districts as well.

The material contained in this paper can afford no information as to the exact position

TABLE III

Type of malignant tumour	Sex	Community	AGE GROUPS								Age not known	Total
			1-10	11-20	21-30	31-40	41-50	51-60	61-70	71-80	81-90

of malignant disease in the vital statistics of this province. It can, however, testify to the definite presence of malignant disease in the province and its not insignificant rôle as a cause of mortality and morbidity. Although

TABLE V* (a)

Number of cases of new growths (malignant) treated in the Punjab from 1923 to 1931

Year	Total treated	Total deaths
1923	799	62
1924	1,951	51
1925	2,157	71
1926	2,235	72
1927	2,813	64

the autopsy and biopsy figures handled are small, the inference is not unjustifiable that the incidence of carcinoma in the two sexes is about equal, that the age period for highest

TABLE VI

Year	TOTAL NUMBER OF PATIENTS TREATED		TOTAL NUMBER OF CASES OF MALIGNANT DISEASE TREATED	
	Out-door	In-door	Out-door	In-door
1923	34,872	5,604	119	156
1924	33,524	5,743	92	152
1925	36,955	6,720	139	153
1926	37,777	7,158	122	127
1927	41,459	7,506	193	194
1928	45,380	7,622	211	142
1929	46,625	7,568	164	93
1930	53,435	7,912	188	123
1931	57,387	8,044	248	159

incidence of cancer is from 40 to 50, and not from 50 to 60, as is the case in Japan, most European countries and the United States of America, and that cancer of the breast and reproductive organs is commonest among females and of surface epithelium in the male. The figure for cancer of the penis is not as high as in some other countries, and cancer of the gastro-intestinal tract and liver is not so common as in the Far East, the Dutch Indies and probably in Southern India. The proportion of carcinomata to sarcomata is, as in some other countries, about 3:1. The maximum incidence of sarcomata is, as in the Chinese and Europeans, at a younger period (20 to 30). The incidence is not, more or less equally, distributed over all age periods, as is said to be the case among the Javanese.

Until such time as economic and educational progress makes it possible for proper vital statistics to be collected in this country, reports of autopsy and biopsy examinations ought to be obtained by some central agency from all pathological laboratories in India and statistics affording an insight into the problem of malignant disease obtained. In suspected cases of malignancy it should be made possible for any registered medical practitioner in attendance to obtain free of charge from any Government pathological laboratory a report on material submitted for histological examination.

A NOTE ON THE USE OF MARMITE IN TROPICAL MACROCYTIC ANÆMIA, INCLUDING PERNICIOUS ANÆMIA OF PREGNANCY

By LUCY WILLS, M.B., B.S. (Lond.), M.A. (Cantab.)

Haffkine Institute, Parel, Bombay

In an earlier paper the use of *Marmite*, a yeast extract, in the treatment of tropical macrocytic anæmia was reported (Wills, 1931). Since this publication other workers have recorded varying results with this line of treatment. Vaughan and Hunter (1932), Goodall (1932), and others have reported success both in macrocytic anæmia in cases of idiopathic steatorrhœa, and in certain cases of true pernicious anæmia. Mudaliar (1932) reports unfavourably from Madras, Green-Armytage (1932) favourably from Calcutta. Unpublished figures from other parts of India are favourable.

In a paper to be published shortly a full account of the treatment of this anæmia will be given, but as further trials have confirmed my previous findings as to the curative action of this preparation, the following notes as to its use and limitations may be helpful to other workers, wishing to make a trial of this remedy.

1. It is essential that the diagnosis of pernicious anæmia of pregnancy or tropical macrocytic anæmia should be made on an accurate examination of the blood picture. Experience in Bombay suggests that both marmite and liver extract are used very frequently in microcytic secondary anæmias, mistakenly diagnosed as pernicious anæmia on the clinical picture.

Negative results are regarded as evidence of the uselessness of these remedies, a revision of the diagnosis being but rarely considered.

2. Sepsis as a complication must be excluded, and this applies particularly to post-delivery cases, as severe sepsis is well known to inhibit the hæmopoietic effect of both liver extract and marmite.

3. If the response to treatment is to be judged by the reticulocyte rise, reticulocyte counts must be made daily from the third to the tenth day. One worker who reported unfavourably on the curative action of marmite on this basis, in a personal communication said that the reticulocyte count had been made only on or about the tenth or fourteenth day.

4. Marmite to be active must be used in adequate doses and it is essential to see that the dose prescribed is both given and taken. Again from experience in Bombay hospitals, the need for personal supervision in this respect is stressed. In severe cases I am now giving two-drachm doses three times a day. Goodall's patients took half an ounce, three times a day. Vomiting rarely occurs if the medical adviser personally sees that the dose is properly given. Diluted with three or more ounces of iced water, with ice or sour lime to suck immediately after, it rarely causes nausea, especially if the patient is reassured. Given as a soup, with

the addition of some vegetable or meat stock, well flavoured to taste, many patients like it and find it appetizing.

5. In desperately ill cases, when digestion and absorption are very greatly reduced or absent and time is of the greatest importance, the best line of treatment is intramuscular or intravenous injections of liver extract combined when possible with a small transfusion. After the first few days, if there is any response, the injections may be replaced by liver or marmite by mouth. But in the majority of cases, even

those with counts as low as one million, the response to marmite in adequate doses is so rapid that the more expensive treatment is rarely necessary.

6. A few cases may not respond to treatment with marmite, when it may be assumed that the intrinsic factor of Castle (1929 and 1930) is missing. Such cases are extremely rare in Bombay; hidden sepsis is a far more frequent cause of failure.

The response to treatment in two typical cases is shown in the accompanying charts.

INTENSIVE IRON TREATMENT OF ANÆMIA IN A TEA-GARDEN LABOUR FORCE*

By RASAMAY BHATTACHARYYA, L.M.P.

Bokpara Tea Estate Hospital, Doomdooa, Upper Assam

PRACTICALLY all anæmic patients are treated as in-patients. On the day of admission oil of chenopodium is given, which is repeated once weekly so long as the patient is in hospital. The iron treatment (*ferri et ammonii citras*) is started from the second day and continued until the hæmoglobin value of the patient's blood is 60 per cent. or higher.

We gave one drachm of *sodii sulphas* along with each dose of iron in a mixture to counteract constipation, but sometimes bigger doses of *sodii sulphas* are required. Purgatives can also be given separately, when necessary. In fact, a saline aperient is an essential accompaniment of this treatment. Other conditions were treated symptomatically as they arose.

Altogether 80 cases were treated. In order to study the effect of various doses they were divided into three groups. The first group consisted of 9 patients getting at the start a daily dose of 60 grains of *ferri et ammonii citras*, which was gradually increased to 90 grains daily. The second group consisted of 18 patients getting at the start a daily dose of 60 grains, which was gradually increased to 120 grains daily. The third group consisted of 53 patients getting at the start a dose of 90 grains daily, which was gradually increased to 120 grains daily. The hæmoglobin estimations were made by Tallqvist's scale. The details are shown in table I.

	Group 1	Group 2	Group 3	Average of 3 groups
Number of cases treated.	9	18	53	..
Average time on the anæmic list in months.	15.7	13.6	5.8	11.7
Average daily dose in grains.	70	94.2	97.3	87.2
Average hæmoglobin percentage on admission.	30	33.9	45.1	36.3
Average hæmoglobin percentage on discharge.	60	60.8	63.3	61.3
Average length of treatment in days.	28.4	18.8	10.8	19.3

The following facts emerge from the above table :—

- The chronicity of the cases.
- The low level of hæmoglobin percentage on admission.

* Rearranged by editor.

(c) The efficacy of iron—the bigger the dose, the better and quicker the result.

Table II has been prepared from group 3 only; of this group, 29 patients had hæmoglobin of 45 per cent. and less on admission, the average being 40.1 per cent.; the remaining 24 had hæmoglobin above 45 per cent. on

TABLE II

(Showing the difference in the effect of iron according to the degree of anæmia on admission.)

	HÆMOGLOBIN	
	45 per cent. or less	Over 45 per cent.
Number of cases treated ..	29	24
Average daily dose in grains ..	102.4	91.2
Average hæmoglobin percentage on admission.	40.1	51
Average hæmoglobin percentage on discharge.	62.4	64.4
Average length of treatment in days.	13.4	7.7

admission, the average being 51 per cent. All these 53 patients had uniform treatment, as shown above, that is the daily dose was started at 90 grains and increased to 120 grains. It is obvious from this table that the higher the percentage of hæmoglobin on admission, the quicker the result and the less the dosage required.

Influence of diet.—Owing to the present economic crisis, no special dietary could be arranged. The patients were given a little chicken soup thrice weekly in addition to the usual *dal* and vegetable curry; this was supplemented, when possible, by a little milk. Considering the modesty of the diet supplied, I have no reason to believe that the diet accentuated the effect of the iron.

Influence of sex.—This series consisted of 55 women and 25 men, that is the women formed 69 per cent. of the total cases; there was no difference in progress between the two sexes. Among females themselves, there was no difference in response between the unmarried, married, nulliparæ, primiparæ and multiparæ.

Influence of age.—The average age of women was 24.1, the highest being 44, the lowest 12; the average age of men was 32.4, the highest being 62 and the lowest 12. The average age of both women and men combined was 26.7. People of all ages progressed uniformly except one of 62 years of age who appreciably lagged behind. The treatment may have, I presume, less effect on patients of advanced age.

Influence of caste.—This series consisted of 16 different castes, the Doms, Oriyas, Mohalis and Telengas predominating; all responded

equally well except the Telengas who were somewhat late in response. These Telengas are primitive in their habits and have a low standard of life.

Iron therapy in anæmia of pregnancy.—Four cases of anæmic pregnant women were treated, two being of the secondary type and two of pernicious type (diagnosed by the necessary hæmatological examination); the former two responded quite well, but the latter two did not. Pernicious anæmia of pregnancy is quite a separate disease which does not respond to iron therapy, so these two cases have not been included in this series.

Relapses.—Relapses after treatment are not uncommon. Five of this series, that is 6.2 per cent. of the cases treated, relapsed, three cases after four months and two cases after three months. So it appears that the effect of treatment on at least a certain proportion of cases is not lasting.

Complications.—Besides constipation two patients complained of abdominal pain, one of anorexia, and another of giddiness. All these complaints were relieved by a brisk saline purge.

Failures.—There were four cases in which response to treatment was unsatisfactory; two were men, aged 62 and 32, respectively, age being possibly the cause in the first case, and two women, aged 18 and 15 respectively; endocrine dysfunction may have been the cause of the failure in the first, and in the second it was almost certainly chronic malaria.

1. ECONOMIC ASPECT OF THE TREATMENT

In table I the average daily dose has been calculated as 87.2 grains, and average time required for treatment as 19.3 days. Therefore the total average amount of iron required in a case is 87.2×19.3 grains, that is $3\frac{1}{2}$ ounces approximately, which costs annas seven only. We know of no other treatment cheaper than this. From the economic standpoint, it may be pointed out that apart from the gain in work, the number of anæmic coolies receiving a special diet has come down from 39 to 5, which is not a negligible saving.

Secondly, along with the disappearance of anæmia the powers of resistance to diseases is likely to be increased. The salutary effect will be noticed mostly in the women coolies who form the bulk of the anæmic patients, and we may expect a diminution in the death rate amongst pregnant women and in the number of marasmic, premature, and still-born babies.

ACKNOWLEDGEMENTS.

I am indebted to my chief, Dr. D. P. Williams, for his valuable instruction in treating these cases and his kind permission to publish the records, and to the manager, Mr. H. O. J. Maxwell, for his unfailing support in this, as in other details of hospital administration. My thanks are also due to my compounder staff for their loyal co-operation in this undertaking.

A NOTE ON THE PREVALENCE OF LEAD POISONING IN INDIA

By R. H. CANDY,

LIEUTENANT-COLONEL, I.M.S.

Civil Surgeon, Ahmedabad

It is a melancholy thought to our profession, as Sir James Mackenzie pointed out, that a large percentage of cases of all kinds are never diagnosed. We may take comfort from the fact that a good number of such are cases of lesser ailments, the duration of which does not permit much investigation, but the position would be more serious if a suspicion should arise that major ailments also were escaping us.

There appeared recently in the *British Medical Journal* an article by Professor Bramwell (1931) on the subject of lead poisoning, which might have attracted much attention in this country, since it emphasised the protean character of the manifestations of this disease and should have suggested at least an occasional solution of the complexity of some of the cases with which we have to deal.

The object of this note is to invite the attention of practitioners to the prevalence of lead poisoning in this country. I do not propose to discuss its symptomatology or treatment as these are fully dealt with in all the standard textbooks, but I wish to warn practitioners of the necessity of keeping this disease in mind.

It must be the common experience of those of us who handle many outpatients to meet a large number of cases which defy speedy diagnosis. I will take only two instances, (1) vague abdominal pain, and (2) irregular nervous syndromes.

(1) From time to time cases arrive at hospital with severe abdominal pain and other symptoms suggesting intestinal obstruction. Such cases demand the most anxious consideration as to whether to operate or not, and every faculty is called into play to assist in the decision. Eventually many such cases are left alone, given anti-spasmodics, and the next day they are found to be much better. On the other hand some are operated upon and another successful appendicectomy is added to the list! I suggest that many of these cases are examples of lead colic.

(2) Although cases of nervous disease are common enough, it is curious that only a small number can be labelled with one of the names so common in England. Nearly all the cases seen are cases of atypical combined lesions.

In fact if we were to consider what is the commonest form of recognisable nervous disease we should be forced to say progressive muscular atrophy. Most of us must have seen a number of examples of this disease, and usually atypical in one respect, namely the age of the patient. This view may be compared with the fact that wasting of the hand muscles is one of the typical lesions of lead poisoning.

Examination of the usual type of combined tract lesions has frequently suggested that the case is one of meningo-vascular syphilis, and the evidence of a positive Wassermann reaction may often confirm this view. Further, anti-syphilitic treatment in certain cases produces marked benefit, and there can be no doubt that this type of disease is not uncommon. But a residuum of cases remains, which although they may give a positive Wassermann, do not benefit from treatment, and I suggest that a number of these will be found to be cases of plumbism. Illustrations will be afforded by the cases quoted.

A case of nephritis is also quoted, and confirmation has been found for the textbook statement that urine excretion is often deficient in plumbism. The blue line on the gums, regarded as a classical symptom has not been noted quite as described. It is not usual to find a blue line on the dental margin, but to find blotchy patches on any part of the gums.

If we accept the fact that plumbism is by no means uncommon in India, it is next necessary to consider how the disease is contracted. There can be little doubt that the principal source is from the habit of "tinning" vessels. The tin which is used for this purpose is frequently adulterated with lead. The adulteration may be deliberate, or fortuitous.

The poison may then be conveyed by cooking in such vessels, or by the use of such vessels for storage, particularly of ghee. Ghee kept in tinned vessels may be found to show green spots. These green spots are composed of lead oleate.

This question seems well worthy of the attention of the Indian Research Fund Association.* If these findings can be confirmed independently, legislation might follow which would control an entirely preventable cause of disablement.

A summary of a few cases is appended.

I should like to express my thanks to Drs. Mankad and Fozdar for their energetic co-operation in making these investigations and providing the case summaries, and not least to Mr. J. D. Anklesaria, lecturer on chemistry at this school, who has carried out all the chemical investigations.

Case 1.—A married girl, aged about 20, was admitted in the hospital with 3 or 4 months' history of menorrhagia and metrorrhagia—the bleeding was enough to cause anxiety and was immediately responsible for the patient's seeking of admission to hospital. When admitted she was stated to have been mentally incoherent for a year; she had gradually developed spastic paraplegia, with marked ankle clonus and Babinski's sign for the last eight months and nystagmus, but without any sensory or sphincter trouble. The patient was very pale and had patches of dermatitis on the limbs and trunk.

*The reader's attention is drawn to a paper by Lieutenant-Colonel T. C. Boyd, I.M.S., and Dr. H. D. Ganguly, which appeared in the *Indian Journal of Medical Research* of July, 1932. A résumé of this is given in our 'current topics' section.

While demonstrating the case to the students, disseminated sclerosis, subacute combined degeneration, cerebro-spinal syphilis, progressive muscular atrophy, spinal tumour, and plumbism were considered. The Wassermann reaction was negative and on the grounds of spastic paraplegia, plumbism being excluded, a tentative diagnosis of disseminated sclerosis was made. The demonstrator learnt from the article of Professor Bramwell referred to above that spastic paraplegia could occur in plumbism and he then looked for a blue line on the gum, which was not there. On inquiry the patient was found to have had an abortion 2 years ago and as the pallor and uterine bleeding could not be explained by his diagnosis of disseminated sclerosis, the urine of the patient was examined for lead. Heavy traces of the metal were detected by the chemist, and the diagnosis settled. A little over three months after, the patient left the hospital, walking unsupported though with an element of spasticity, mentally much improved, without any pallor, with a normal skin, and normal menstrual functions.

Case II.—A married male, aged 32, had rather rapidly developed peripheral neuritis without any fever, with a negative Wassermann reaction and without any colic but with a constipation for a few months prior to the neuritis. There was no nystagmus. The neuritis was more of motor than of sensory type though the sensory system was by no means entirely free. While considering the ætiology of the neuritis, lead was thought of. A blue line on the gums was seen easily and the urine was sent for the examination of lead; this was detected. He was treated with sodium thiosulphate intravenously and potassium iodide orally and is on his way to recovery within four months.

Case III.—A married girl, aged about 18, 5 months pregnant, came to the hospital with a badly distended abdomen and the bowels completely locked for 6 days, the coils of the intestines appearing like a ladder under the abdominal wall, there was no vomiting, a clean tongue, a good pulse, and a good general condition. She gave a history of similar attacks for the last ten years, recurring every 6 or 8 weeks and lasting a day or two. She sought admission when she found that the attack had lasted 2 days. In this case the blue line on the gums was searched for and not found. The diagnosis of partial obstruction of the gut was made and the surgeon was summoned in consultation. The latter refused to operate unless vomiting set in or the general condition demanded it, lest premature labour might be precipitated. The patient improved on concentrated magnesium sulphate and hyoseyamus and went home a week later. Next week she was admitted again with signs of uterine bleeding, which ended in a premature delivery. While convalescent from it in the hospital she had again the attack of distension of the abdomen, obstinate constipation, etc. This compelled a urine examination for lead, which was found.

Case IV.—A school boy, aged 12 years, suffered from fever for about 2 months from February 1932, during which time he developed mitral stenosis. In April he attended for low fever and severe dyspnoea. A diagnosis of pericardial effusion was made and was confirmed by x-rays. A partial recovery from it was made by July 1932, when he was seen a second time for oedema all over the left side of the body and left pleural effusion. The oedema soon extended to the right side, but remained always more on the left. There was oliguria and the urine showed much albumen with a trace of sugar, and marked acetonuria. There was definite starvation prior to these symptoms. The diet being limited to a small quantity of boiled milk and very occasionally some bread. The diagnosis of avitaminosis was made by a consultant, and vitamins and a good diet were prescribed. No improvement followed a fortnight's trial. This having been pointed out to the consultant, the latter ordered a urine examination for lead and the report from the chemist showed that this diagnosis was correct.

Case V.—An educated man was going home from work

A NEW CORNEAL SCRAPER FOR TATTOOING

By JADAVJI HANSRAJ, D.O.M.S. (Eng.),
L.M. & S. (Bom.)

Fateh Manzil, New Queen's Road, Bombay

TATTOOING of very dense opacities of the cornea for æsthetic as well as for optical purposes is quite an old operation. The material commonly used was Indian ink which was introduced into the deep parts of the cornea with either a grooved tattooing needle or an instrument consisting of a number of fine needles in a handle. The results of this small operation were not always very satisfactory, and in a number of cases the effect did not last very long. To remedy these defects, a new technique was devised by which permanent colouring of the cornea could be effected.

The little operation is done as follows :—

The eye is anæsthetised, preferably with butyn 1 to 2 per cent., instilled twice at an interval of five minutes. Cocaine should be avoided as far as possible on account of its drying and exfoliating effects on the corneal epithelium. The eye is washed with a 1:5000 hydrargyri perchloridum solution and later with sterile distilled water. Saline is not to be used on account of its decomposing effects on the solutions used for tattooing. The next step is to scrape off the superficial corneal epithelium. Ordinary Graefe's knives, secondary knives, scalpels, discission needles, pterygium knives and many other instruments have been used to scrape the cornea, but not being satisfied with any of these instruments, I have devised a special corneal scraper of which an illustration is given herewith. The corneal epithelium is very lightly scraped, particular care being taken to scrape the margins of the opacity. If care is not taken in doing this, the result is a black-coloured central spot with white linings. In scraping the cornea, one has to be very particular in those cases where there is partial anterior staphyloma and the iris lying closely matted with the spurious cornea; if care is not taken here, the resulting uveitis may be so

(Continued from previous column)

one evening, after a period of heavy strain, when he fell down in the road and became 'unconscious'. He remained 'unconscious' for three days after which he was brought to Ahmedabad. When seen he was mentally confused, cerebation was very slow, paraplegia was present and he could not sit up; paræsthesia was noted but this might have been an association of the mental confusion. Blue patches were found on the gums and a diagnosis of lead encephalopathy with other evidence of plumbism was made and confirmed by urinary analysis.

The patient rapidly improved, and could walk with assistance within ten days.

as a case of sandfly fever, and developed severe vomiting and restlessness after 2 days. There was no change in breath sounds and no dullness on examination of the lungs. On blood examination, no malaria parasites were found and there was no leucocytosis. Crepitations at the bases of both lungs previously present were still audible after 4 days; urine examination revealed a large amount of urobilin; when he was treated as a case of malaria, with quinine, he was completely freed from all symptoms within two days.

Case 2.—The patient, a teacher, was reported to be suffering from severe dysentery and temperature of 100° to 101°F. for 2 days. On examination he was found collapsed with cold clammy sweat and a feeble pulse. He passed about 20 ounces of blood in the stools on two occasions during the day. There was a frequent tendency to vomiting; the spleen was just palpable. There was no mucus in the stools, the urine was found full of urobilin, and blood films full of malignant tertian malaria parasites; he was treated as a case of malaria fever and had no recurrence of blood in the stools or of vomiting.

The vomiting tendency as in the previous case suggested malarial infection; urobilin in the urine and the blood findings confirmed it.

Choleraic symptoms in malarial infections are frequent, but the passage of pure blood in the stools is very infrequent; the case is therefore interesting on this account.

Case 3.—An Anglo-Indian, employed in a European firm, suffered from hæmaturia and slight fever. Blood culture was negative. No definite diagnosis was made as the patient recovered after 36 hours' illness. Ten days later he developed symptoms of acute dysentery and passed about 40 stools full of blood, in the course of a few hours. His temperature was 104°F. Malaria parasites were found in his blood and urobilin in the urine. He was treated with quinine and recovered quickly.

Case 4.—A young man of 28 years, with a history of attacks of biliary colic and an enlarged tender gall bladder suggesting cholecystitis and cholelithiasis; urine examination showed the presence of a large amount of urobilin and a skiagram after Shadocel confirmed the presence of stones in the gall bladder.

Cases of cholecystitis on account of the associated cholangitis also show an increased amount of urobilin, and the presence of urobilin in cases of cholecystitis is sometimes of diagnostic value.

In three cases of cholecystitis and cholelithiasis, diagnosed by symptoms and confirmed by x-rays, a large amount of urobilin was present.

In 11 cases in this series where the blood films showed malaria parasites and urobilin was absent in the urine, some were afebrile and possibly blood destruction was not marked; in others the temperature was present for only a few hours, when the blood films were examined, and urobilin had not yet appeared in the urine. There were, however, four cases where fever was present for three to four days, and showed malaria parasites without the presence of urobilin in the urine. Such cases are exceptional and difficult to explain.

In 20 cases, where malaria parasites were found in the blood films and urobilin was present, estimation of urobilin in the specimens of urine submitted was done by the following

method, as recommended by Elman and McMaster (1925) and modified by the writers in the expression of results.

A standard solution of acriflavine containing 1 milligramme of acriflavine dissolved in 30,000 c.cm. of distilled water, representing 1 unit (equivalent to 1 milligramme of urobilin dissolved in 950 c.cm. of the standard diluent) was prepared and the urobilin estimated as follows:—

Take 10 c.cm. of urine; add 1 drop of Lugol's iodine solution and 10 c.cm. of saturated solution of zinc acetate in absolute alcohol, filter through filter paper and compare with standard solution. It is best to prepare a stock solution of acriflavine containing 10 milligrammes of acriflavine in 1,000 c.cm. distilled water and from this to prepare standard solutions by diluting 1 c.cm. of this stock solution in 50 c.cm. distilled water and 1 c.cm. of the stock solution in 100 c.cm. distilled water, representing 6 units and 3 units of urobilin, respectively. It is advisable to use test tubes with a length of 10 inches and a bore of $\frac{1}{2}$ inch. These tubes may previously be marked with a glass pencil to represent volumes of 5 c.cm. Comparison is best made in a tropical country in direct sunlight using a Cole comparator, with the light falling on top of the liquid through the open end of the test tubes. Amounts varying from 0.01 to 0.5 or 1 c.cm. of the filtrate were taken, diluted with the following diluting fluid up to the 5 c.cm. mark.

Composition of the diluting fluid

Sixty per cent. alcohol—1,000 c.cm., zinc acetate—25 gr., concentrated hydrochloric acid 1 c.cm. filtered, repeated till perfectly clear.

Standard solutions representing 3 units and 6 units, respectively, were placed in adjacent compartments of the Cole comparator with the diluted filtrate in the middle compartment and the result compared.

Gradually increasing amounts of the filtrate were added to the middle tube containing the diluted filtrate to make the colour match first with the three-units tube and then the six-units tube.

Suppose 0.01 c.cm. of the filtrate diluted to 5 c.cm. matched with the standard representing 3 units; the number of units in the filtrate is $\frac{3 \times 5}{0.01}$ or 1,500 units, and, since the urine had been originally diluted with an equal amount of reagent, it will have 3,000 units. In this estimation the precipitate produced is neglected. It is a rough and ready method of finding the amount of urobilin in urine.

Calculated in this way, urobilin units varied within very wide limits, therefore no hard and fast limit could be laid down as to the presence

(Continued at foot of opposite page)

LIFE TABLES FOR BENGAL, WITH NOTES ON THE METHOD OF PREPARATION OF LIFE TABLES

By H. P. CHAUDHURI, M.B. (Cal. U.), D.P.H. (Lond.), D.T.M. & H. (Lond.), F.R.S.S. (Lond.), D.O.M.S. (Lond.)

(Hony. Research Worker, All-India Institute of Hygiene and Public Health, Calcutta)

ONE way of expressing the death rates experienced by a population in a given period of time is by means of a 'life table'. This gives a concise yet comprehensive table of survivorships up to any given age, and the prospective duration of life from that age onwards. A life table facilitates comparison between different places and between different periods as regards the expectation of life of the populations. Further, an exact statement of the average duration of human life from birth or from any subsequent age can only be given by the means of the life-table method. Life tables, however, do not actually trace the same persons throughout life, but assume that a given number of persons are subjected throughout the whole of their lives to the death rates of a given group of years.

Thus we see that a life table can be used in a number of ways. It supplies the information regarding the probability of living or dying at each age. Next it gives the probability of surviving 5, 10, 15 years and so on. Then again we can ascertain the number of survivors out of, say, 10,000 children at the end of each year of life, until the whole number becomes extinct

(Continued from previous page)

of urobilin units before a patient could definitely be diagnosed as one of malarial fever. However, the greater the amount of urobilin the greater the suspicion of malaria infection in a febrile case.

Tests to detect the presence of urobilin in urine were the same, as were given in the *Indian Medical Gazette*, May, 1931, p. 241.

Summary

I. Four important conditions in the tropics, particularly in the Punjab, in which urobilin is present in large amount are in order of importance—malaria fever, lobar pneumonia in the resolution stage, internal hæmorrhage, and cholecystitis.

II. The presence of a large amount of urobilin in the urine differentiates cholecystitis from kidney lesions, appendicitis and other abdominal conditions.

III. The condition in which urobilin is present in the largest amounts is malaria infection.

All the members of the pathology department, King Edward Medical College, worked together in this investigation.

by death, and lastly the table enables us to estimate the expectation of life at the end of each year of life. The last two supply composite information regarding the average past and average future. It is needless to point out how valuable this information is, not only for students of public health, but also for insurance companies.

Now a life table can be constructed by tracing the lives of a number of children from birth to death, but if followed in practice this method would be of no real value, as the table when completed would be out of date. The alternative method, the method commonly used, requires that we should ascertain the population and the deaths for each year of life; this is the method which the writer has actually adopted here. There is a third method, that is, by actually tracing the lives of a selected group for a certain number of years, as is done in insurance practice.

The life table has six important columns, $P_x, d_x, q_x, p_x, l_x, o_{ex}$. To construct a life table only one piece of information is needed and that is the 'rate of mortality'. The expression 'rate of mortality' is used technically to denote the ratio, represented symbolically by q_x , of the number of deaths in a particular age group, x to $x + 1$ years, to the number of persons entering upon that year of age. The successive values of q_x can be derived by means

of the formula $q_x = \frac{d_x}{P_x + \frac{1}{2}d_x}$, where d_x represents

the average number of deaths of persons of ages between x and $x + 1$ years, per annum, and P_x the average number of persons enumerated at the census as having been aged x at their last birthday, i.e., persons aged between x and $x + 1$. Therefore the number of persons aged x exactly is the number of the census population, i.e., P_x plus the number of deaths occurring in the first half of the year, i.e., $\frac{1}{2}d_x$. Thus, the rate of mortality depends on two things d_x and P_x .

Now the values of d_x , the average number of deaths at each year of age in a given population, can be ascertained from the government annual reports of vital statistics, and those of P_x , the number of persons of each sex at each last birthday, can be ascertained from the census report.

The basis of the investigation having been thus determined, it becomes easy to obtain directly from the data a measure of the mortality experienced in the country during the period at each age by means of the ratio already mentioned, i.e.,

$q_x = \frac{d_x}{P_x + \frac{1}{2}d_x}$, from which the factor, p_x , can easily be calculated by $p_x = 1 - q_x$. Having ascertained p_x , the number living at each age (l_x) is obtained by multiplying the

*For definitions see list at end of paper.

number living at the immediately preceding age by p_x , e.g., $l_x = l_{x-1} \times p_x$.

The final column O_{ex} , known as the 'complete expectation of life', is the average number of years lived (subsequently) by persons who reach the age of exactly x years. The value is determined by the equation $O_{ex} = \frac{x+1 + l_{x+2} + l_{x+3} + \dots + l_{x+(n-x)} + \frac{1}{2}}{l_x}$

years. Now in the case of Bengal n is 90, which is the maximum age lived in this province. The values of the series $l_{x+1} + l_{x+2} + \dots$ cannot be obtained unless we calculate all the values right up to the last figure, $l_x + (n-x)$, or l_{90} in the case of Bengal, and work backwards; the whole series, $l_{x+1} + l_{x+2} + \dots$, can be symbolized by T_x , the various values of which are shown in a column in the tables III (a) and III (b). The T_x for each age is thus obtained by adding the figures in the l_x column up as far as the year in question, e.g., in table III (a), $7 + 13 = 20$, $7 + 13 + 21$ (or $20 + 21$) = 41, $41 + 32 = 73$, etc., so that $T_x = l_x + T_{x+1}$.

O_{ex} thus equals $\frac{T_x}{l_x} + \frac{1}{2}$ years.

Criteria for comparison

The criteria adopted for the comparison of the life tables of different epochs and different places are as follows:—

- (1) At a selected age, the probability of dying before some later age is reached.
- (2) The number of survivors at a selected age out of a stated number of births.
- (3) The expectation of life at birth, or at some selected age.
- (4) At some selected age, the probability of surviving an indicated number of years, say 10 years.

Some authorities on the subject of life tables consider that (4), of which (1) may be regarded as a corollary, is the best criterion of the characteristic of a mortality experience, though the expectation of life at birth provides a comprehensive figure, which summarizes the whole table, and is the figure most often quoted to indicate the state of health of a population.

It is clear that 'the expectation of life' has but a 'mean' value and, like every other case of a mean value, it suffers from the defect that it gives no information of the dispersion round the mean. For instance, to state that the average height of an Indian government servant is 5 feet, gives a good indication of the height of each individual, but to say that their average pay is Rs. 40 gives little indication either of the pay of sweepers in Writers' Building or the pay of a Member of Council; in the former case the dispersion round the mean is small, whereas in the latter it is very large.

Examples

- (1) At the age of 20 years, what are the respective chances of a Bengali male and a Bengali female surviving to the age of 40 years?

From the l_x columns of tables IV (a) and IV (b) the numbers of the survivors at the age of 20 and at the age of 40 can be seen; they are 4,432 and 2,910 for males, and 5,035 and 3,296 for females. The chances of survival are, therefore,

$\frac{2910}{4432} = 0.6565$ for males, and $\frac{3296}{5035} = 0.6546$ for females and the chances of dying are thus, $1 - 0.6565 = 0.3435$, and $1 - 0.6546 = 0.3454$.

(2) Out of 1,000 births how many males survive to the age of 20 years?

Again column l_x gives the number of survivors at this age out of 10,000 births, namely 4,432. The number of survivors out of 1,000 is therefore 443.2.

(3) How long may a man who has reached the age of 20 years expect to live?

This figure is taken directly from the O_{ex} column; it is 29.43 years, that is, he will probably live to the age of (20 + 29.43 or) 49.

Life table for Bengal

Hitherto only two life tables for Bengal have been published—one on the population basis of 1891–1901, and another on that of 1901–1911. The late T. G. Ackland, the celebrated actuary, was responsible for both of them. No life table has been constructed for the last 20 years. This is a very undesirable state of affairs in view of the growing importance of the subject. The data on which life tables are constructed in this country are often not very dependable on account of the omissions and misstatements that are to be found in them. These errors can be adjusted by the process known as 'graduation'. Here only the method by which the present table was constructed will be discussed.

In the *National Life Tables of England and Wales* we find that to construct a life table one should know the population living or dying in each year of life, but often we only know the population and the deaths in wider age groups, e.g., 0–5, 5–10, 10–15, and not at each year of life. In such cases we must reach the value for each year of life by some method of interpolation (mathematical or graphical). Having by some such method reached our population and deaths at each year of life, we can determine the probability of dying or living at any age by the methods already discussed.

To find out the population at each age (P_x), we have based our calculation on the census figures of 1921, using the groups 0–1, 1–5, 5–10, 10–15, 15–20, 20–30, 30–40, 40–50, 50–60, and 60 and up, years.

In order to arrive at d_x , the deaths at each age, we have taken the figures of deaths from the annual reports of deaths of the year 1920, 1921 and 1922 (see table I) and have calculated the average of these three years as representing the death rate of 1921, for each of the age groups 0–1, 1–5, etc.

To find out the rate of mortality of each group (q_x), we have used the formula $q_x =$

$\frac{d_x}{p_x + \frac{1}{2} d_x}$ where d_x etc., applies to the larger

groups (e.g., 1-5, 5-10, etc.), as d_x etc., applied to each individual year (see table II). To find out p_x , we have deducted the values of q_x from 1.

Then the succeeding values of p_x for each age have been determined by graphical methods of interpolation, and from these q_x and l_x can be calculated by the methods already described above, i.e., by using the formula $q_x + p_x = 1$, and $l_{x-1} \times p_x = l_x$.

The final column ($O_{e,x}$), the complete expectation of life, has been obtained from the column T_x , which represents the sum of number of years lived by the persons who reach age x , as explained above, from the equation $O_{e,x} = \frac{T_x}{l_x} + \frac{1}{2}$ years.

To obtain the values for the years of age under 5, we should not utilise the census population, because it has been shown that, though the total population under 5 may be correct, the population under each individual year of age cannot possibly be correct. To obtain the population of these individual ages the returns of births and deaths are utilised. Knowing the births for the 5 years previous to the census and the deaths at ages under 5 for the same year, we can calculate the population at individual ages at the census time; this is what is actually done in English life tables.

In our present table we have taken the mean of the total births of 1920, 1921 and 1922, and that has been taken as the population between 0 and 1. For the rest we have taken the census figures only. We know at age 0 to 1 it is inaccurate to assume that half the deaths take place in the first six months of life and half the deaths in the second six months. The proportion is rather 70 to 30—so instead of taking $\frac{1}{2} d_x$ to obtain q_x for age 0, we have taken $\frac{7}{10} d_x$. No great error will be introduced by taking $\frac{1}{2} d_x$ at the other ages.

Conclusion

Resting as it does on incorrect data, though the only data available, the present table has only a limited value, but it will provide important material for comparison which should convey sound impressions regarding the value of progressive policies in respect of sanitation, education, etc., to medical men and welfare workers that are not themselves thoroughly conversant with statistical methods.

The different functions used are summarised for easy reference:—

- l_x = the number of persons surviving at the exact age x years.
- d_x = the deaths in the year of age x to $x + 1$ among the persons, who enter on that year.
- p_x = the probability of a person aged x living a year.
- q_x = the probability of a person aged x dying within a year.
- $O_{e,x}$ = the complete 'expectation of life' or the total future life time, which on the average will be passed through by a person aged exactly x .
- T_x = the sum of the number of years lived (subsequently) by all the persons reaching the age x .

A Mirror of Hospital Practice

REPORT ON A CASE OF TUBERCULAR IRITIS

By E. O'G. KIRWAN, F.R.C.S.I.

LIEUTENANT-COLONEL, I.M.S.

Professor of Ophthalmology, Medical College, Calcutta

Miss A. D., Bengali girl, age 16 years. Height—5 feet. Weight—6 stones 5 pounds.

Complaint.—Patient came to the Eye Infirmary, Medical College, on the 1st June, 1932, complaining of pain and blurring of vision for about three weeks. The left eye only was affected.

Past history.—There was no history of any previous serious illness but the family history was interesting in the fact that her grandfather died of tuberculosis of the lungs in 1911. Her elder sister died of tuberculosis of the lungs at the age of 11 years about 8 years back. Her grandmother died of tuberculosis of the lungs 4 months back.

Present examination.—The vision in the right eye is 6/6. The left eye is 6/18. The cornea is not involved. The iris shows no acute inflammation, there are some bands of posterior synechiae, and isolated spots of pigment on the anterior capsule of the lens. There are numerous small grey nodules to be seen scattered over the anterior surface of the iris, some at the pupillary margin, some on the collarette, and some at the ciliary margin of the iris. These can be seen in Plate II, which

shows the iris under the corneal microscope and slit lamp.

Diagnosis.—Tubercular iritis. The von Pirquet test is positive. Clinically nothing abnormal can be found in the lungs. X-ray examination shows early infiltration in the right apex and subapical region.

The patient was kept under observation without any local or general treatment for a week after admission into hospital and during this period there was definite increase in the number of nodules. For the past three weeks she has been under local treatment as well as general and her ocular condition has improved, there has been no increase in the nodules and some have diminished in size.

Tubercular iritis whilst common in Europe and America is very uncommon in India. At the Eye Infirmary, Calcutta, we only see very few cases of ocular tuberculosis in the year, yet tuberculosis of the lungs in Calcutta is common. Syphilitic iritis is common and by far the commonest cause of iritis in Calcutta. Tubercular nodules resemble syphilitic nodules but are more numerous, are grey in appearance and do not change colour. They are also scattered irregularly on the surface of the iris. Syphilitic nodules are about the size of a pin's head, are reddish-yellow in colour and as they become vascularised, change colour to a muddy brown. Syphilitic nodules are always situated at the outer or inner margins of the iris, never between.

(Continued at foot of opposite page)

PLATE II

Tubercular Iritis.

THE OCCURRENCE OF HÆMOGLOBINURIA DURING TREATMENT OF MALARIAL FEVER WITH ATEBRIN AND PLASMOQUINE

By N. G. BANERJEE, M.B.

and

PHANINDRANATH BRAHMACHARI, M.Sc., M.B.
Physician, General Hospital, Howrah, and Clinical
Research Assistant, Carmichael Medical College
Hospitals, Calcutta

THE following case is published not with the idea of showing any causal relationship between the development of hæmoglobinuria and the combined administration of atebtrin with plasmoquine, but to point out that these drugs failed to avert an attack of hæmoglobinuria in the patient during their administration.

(1) Patient, B. K. M., had an attack of fever with severe rigors in the third week of last September while staying at the Sunderbans. He was treated with quinine sulphate which was continued up to 1st October. On this day he had another attack of fever with rigors. He then came under the treatment of one of us (N. G. B.) and was given three successive injections of five grains of quinine bihydrochloride after which the fever stopped. He had another attack of fever about ten days after the second, and was again treated with intramuscular injection of quinine bihydrochloride. After four days, he was free from fever and no further quinine was administered to him.

He was put on combined treatment of atebtrin and plasmoquine, two tablets of each being given per day. This was continued for five days. On the fifth day of treatment, he again had fever followed by jaundice and hæmoglobinuria. Next day, he had intense jaundice, the liver was enlarged and tender. There were very marked hæmoglobinuria, severe prostration and some amount of difficulty in breathing. Altogether 15 tablets of atebtrin (gr. $1\frac{1}{2}$ each) and ten of plasmoquine (gr. $\frac{1}{2}$ each) were given to the patient. As soon as hæmoglobinuria appeared, these drugs were stopped. The attack lasted for three days. The patient recovered and is under the observation of one of us (N. G. B.).

During the attack of hæmoglobinuria, the patient was treated with cholesterin, adrenalin chloride, alkalies, and intravenous injection of calcium chloride.

Blood examination—

3-11-32. Red blood cells 2,280,000; Hæmoglobin—32 per cent.; no malarial parasites found.

10-12-32. Red blood cell 3,910,000; Hæmoglobin 60 per cent.

The reticulocyte count was made by one of us (P. N. B.) and is given below:—

3-11-32.	Reticulocyte percentage	.. 7.2
5-11-32.	Ditto.	.. 4.92
10-12-32.	Ditto.	.. 4

(Continued from previous page)

Tubercular iritis is as a rule to be found in association with some latent tubercular affection of the lungs, whether active or cured, as evidenced by calcareous foci at the hilus, fibrous bands, etc.

Treatment.—The treatment of ocular tuberculosis is divided into the general invigorating treatment and the complete local treatment of the eye.

(1) Climatic and constitutional treatment in the mountains.

(2) Tuberculin treatment—Incipient dose small, beginning with (1/100,000 mg.) and increasing up to (1/1000 mg.). The interval between the doses being from 4 to 8 days.

(3) Light therapy by Finsen light or better Röntgen raying with frequently graduated doses.

(4) Subconjunctival sodium chloride injections from 1 to 4 per cent. once or twice a week.

The following points are noticeable in the present case—

- (1) No hæmoglobinuria developed when patient was having treatment with quinine.
- (2) An attack of hæmoglobinuria took place when patient was being treated with atebtrin and plasmoquine.
- (3) The administration of the above drugs failed to avert an attack of hæmoglobinuria.

A CASE OF ACUTE LUPUS ERYTHEMATOSUS DISSEMINATUS

By H. A. MANIAR, M.R.C.P., D.T.M.

Honorary Junior Dermatologist, Sir J. J. Hospital,
Bombay

A PARSİ girl aged 12 was admitted for an eruption over the nose, cheeks and palms; fever and cough.

Origin, duration and progress of the disease.—The present complaint started about 1½ months back. The patient used to get (as she described) low fever intermittent in character. Along with this there was general weakness and lassitude. About a fortnight back she noticed erythematous patches over both cheeks. In spite of treatment, the eruption increased and new patches also appeared forming the typical butterfly or bat's-wing patch across the face.

report the following case, treated with that drug :—

Case record.—On 20th October, a Mahar woman, aged about 20, primipara, was admitted to this dispensary, with a transverse presentation. Under chloroform anaesthesia, internal version was done and the child extracted. The placenta and its membranes came away in about ten minutes. There was no post-partum haemorrhage. Since the day of operation, she began to run a temperature with rigors, ranging between 101° to 106°F. Lochial discharge was first normal but later on it became scanty and foul-smelling. The uterus was tender and there was a hard tender mass in the right iliac fossa.

Treatment.—Hot vaginal douche (iodine) every morning. Cinchona mixture containing strychnine and ergot was prescribed for the first two days for which an alkaline diaphoretic mixture was substituted later. She was given three intravenous iodine injections (21st, 22nd, and 23rd October) two intramuscular injections of quinine on 24th and 25th October, and two intravenous injections of mercuriodrome 1 c.cm. of a 1 per cent. solution in 5 c.cm. of sterile water on 27th and 28th October without the slightest effect on her temperature. On the morning of 29th October her uterus was lightly curetted with a dull flushing curette and her temperature went up to 106°F. in the evening. Her pulse, which had hitherto been below 100, increased to 140 per minute and she became restless. I then resolved to try hydrochloric acid injections. Accordingly I prepared the requisite solution and injected 5 c.cm. of it intravenously at about 5 p.m. The effect was dramatic. Within about three hours, her temperature dropped down to 101°F. and she was normal next morning and remained so until her discharge. The hard tender mass in the right iliac fossa and tenderness of the uterus also disappeared after three more injections.

Dr. Burr Ferguson of Birmingham, Alabama, has advocated the use of hydrochloric acid in the treatment of all manner of infections. The dose recommended is 10 c.cm. of a 1:1500 solution of hydrochloric acid. Injections should be given either intramuscularly or intravenously, daily or two to three times in a week according to requirements of a case.

SYPHILIS OF THE BRAIN*

By D. B. BHATE, L.M.F. (C. P.)

Shree Nath Surgico Medical Hall, Chhindwara

On 14th November, 1932, I saw a patient who was reported to be getting fever for the last two weeks, every afternoon, with rigor. The history was that the patient was unconscious till the next morning, when the temperature used to go down. But since 12th November, 1932, the patient did not regain consciousness though his morning temperature was normal.

He was a male of about 35 years and when I saw him he was in a state of muttering delirium, temperature was 103°F., pulse—130 per minute, respirations—30 per minute, lungs and heart—normal, liver and spleen—not palpable. His bowels were constipated and I gave him a soap-and-water enema, and suspecting it to be a case of cerebral malaria I gave an intramuscular injection of 10 grains of quinine with a diaphoretic mixture every third hour. Next morning the temperature was 97°F., and pulse—100 per minute,

respiration—20 per minute, other conditions being exactly the same, quinine and arsenic mixture 1 oz. every fourth hour was given. Bowels were clear and glucose water with milk and chicken soup occasionally was prescribed as the diet. The patient retained two doses of the mixture but the third and fourth doses were vomited and everything that was administered thereafter was vomited. In the evening the temperature in spite of the quinine mixture rose up again to 100°F.

On 16th morning the temperature was 96°F., pulse—98 per minute, and the patient was in the same condition tossing his head to and fro and in the same state of delirium. Urine was passed into the bed. A carminative mixture with brandy as a stimulant, alternating with euquinine powders, were prescribed for the day. Temperature rose in the evening to 100°F. Since the bowels did not move a glycerin enema was given and another injection of quinine was administered. At night a hypnotic was prescribed.

On the 17th his condition was unchanged. Blood and urine examinations revealed no abnormality.

It was not possible to obtain a definite history, but on the chance of the disease being of syphilitic origin an injection of acetylarsan, three cubic centimetres intramuscularly, was given on the evening of the 18th.

The patient had a good sleep that night and next morning he was looking better and he regained consciousness.

He was then given a mixture of potassium iodide and liquor hydrargyri perchloridi every six hours with marked benefit, so the injection and mixture were continued.

On recovery of consciousness the patient gave a history of syphilis five years previously.

It was not possible to have a Wassermann test done to confirm the diagnosis.

TROPICAL GYNÆCOLOGY AND OBSTETRICS

(A POST-GRADUATE CLINICAL LECTURE)

By V. B. GREEN-ARMYTAGE, M.D.,

F.R.C.P. (Lond.), F.C.O.G.

LIEUTENANT-COLONEL, I.M.S.

Professor of Midwifery and Gynaecology, Calcutta Medical College, and Surgeon to the Eden Hospital for Women, Calcutta

In 1928 I published a plea for vaginal hysterectomy and detailed 150 cases in which this operation had been performed. Since then I have done in this hospital a further series of 136 with one death only. For some reason vaginal hysterectomy is dreaded by gynaecologists in India, and yet there can be little doubt that it has a peculiar attraction for women in the tropics, who will readily face and endure anything that can be performed from below rather than per abdomen.

Doyen, the great French surgeon, used to state, and I have myself heard him, 'that no man should call himself a gynaecologist who cannot perform a vaginal hysterectomy in private'. I think there is a good deal of truth in this for surgeons who are quite amiable in the valleys and dales of the abdomen tremble when working anatomically.

* Rearranged by Editor.

vaginam, for they are unable to visualize up side down. And yet there is really no need to be afraid, tissues are cut, vessels are tied and fascial planes are opened, exactly as one would do if performing a complete hysterectomy from above.

To my mind, fibroids, unless in very fat or debilitated patients, are better treated by operation than by radium, for radium has suffered the fate of every other new remedy in the tropics, in that it has been used indiscriminately without regard to pathology and clinical symptoms, with the result that, in some, intense inflammatory reaction has occurred; in others, where adenomyomata existed, bleeding, growth, and pain increased; in a few, sloughing, accompanied by a stinking discharge has continued for months.

In the tropics of both hemispheres, fibromata of the uterus are extremely frequent and make up some ten per cent. of all operations. They are found in the multipara as often as in the nullipara, and cause much hæmorrhage and invalidism. Provided they are not bigger than a 3-months' pregnancy in a large proportion of cases they can be removed vaginally, provided the surgeon is accurate and fearless in his diagnosis and technique. In a small percentage there may be slight old salpingitis or adhesions between the pelvic wall, but never yet have I found difficulty in separating these adhesions, or been prohibited from finishing any operation vaginally, and compelled to open the abdomen.

Scores of post-graduates and students will bear these statements out, for any week of the year one of these operations is being done.

Out of the last 136 vaginal hysterectomies 56 have been performed for fibromata and 21 for ovarian menorrhagia, *i.e.*, a form of hæmorrhage associated with ovarian dysfunction in which the follicular hormone is in excess or there is absence of the corpus luteum. In 17 the operation has been connected with what I might call the pre-cancerous cervix, *i.e.*, a cervix everted, hypertrophied, eroded and lacerated up to the internal os, bleeding readily at touch and causing anæmia, menorrhagia and distress, for many days every month. You may give this type of cervix any name you wish, but pre-cancerous is what I prefer you to call it, for cancer of the cervix is astonishingly common in the tropics, and this type of cervix is the soil upon which it starts and thrives.

Three cases have been more than usually interesting in that the operations were performed for chorion epithelioma, subsequent to hydatidiform mole. One of these cases was that of a girl who had twice been curetted for hæmorrhage subsequent to the evacuation of a vesicular mole, and on each occasion the pathologist found no evidence of malignancy. Later, she came into this hospital almost exsanguine—a Zondek-Ascheim test was positive, therefore chorionic elements were present. I gave her 18 ounces of blood into the vein that

morning and did a vaginal hysterectomy the next day. She went out of hospital perfectly well and reported alive one year later. The other two cases are alive two and three years later respectively.

In five cases the operation was performed for cancer in the body of the uterus, the tubes and both ovaries being removed at the same time.

In 11 cases the Mayo operation for complete prolapse was performed. These were all old women in whom the operation could be performed in a few minutes without bleeding or shock, compared with that of the Fothergill operation.

Statistics are always dull, but I do want you to realize that the operation of vaginal hysterectomy is of peculiar importance to gynæcologists, and one of particular attractiveness to women in India. Only once have I injured the ureter and once the bladder. You need not ever be afraid of hæmorrhage or shock, or sepsis in cases of vaginal hysterectomy. There are a few points of importance which I stress to onlookers.

(1) Always double ligature the uterine artery.

(2) Always remove both the tubes for they tend to prolapse later into the vaginal wound if you do not.

(3) Always join the bases of the two broad ligaments so that they form an antero-posterior bridge across the pelvis, and thus prevent vaginal hernia later.

(4) Always use stout 21-day catgut and bring the long ends of these catgut threads through the centre of your wound to promote capillary drainage.

(5) Be sure there is no bleeding in either *cul* before closing the pelvic cavity.

(6) Always bring down the peritoneum of the base of the bladder to the edge of your vaginal incision and suture this with interrupted ligatures to the posterior vaginal incision, leaving half an inch gap in the middle line for drainage along with the catgut threads.

(7) Put in a self-retaining or soft rubber catheter for 48 hours.

(8) Fill the vagina with 1 in 100 brilliant green and then plug it tight with several strips of gauze. This is kept in for 24 hours and then removed; the patient being douched twice daily with hot saline for the next six weeks. The catgut then comes out of its own accord and the wound is healed.

(9) My patients get out of bed on the 9th day and usually leave hospital on the 12th.

The operation is really not difficult provided the pouch of Douglas and the utero-vesical pouch are quickly opened. It is the latter incision which apparently is a bugbear to the beginner, but having made the cervical incision if you boldly push up the bladder you will see the thin fish-belly-like membrane of the utero-vesical pouch. Put in an anterior retractor and

then cut this as if it were the frænum of the tongue and you are in the peritoneal cavity. From then onwards the operation is merely a matter of adroitness and anatomy.

The total mortality of my 286 cases is 0.7 per cent. I am perfectly honest when I assure you that a majority of these patients would have never submitted to any abdominal operation. Moreover you must realize that I am not in favour of radium, partly because of the expenses incurred and partly because my experience as a consultant has given me small confidence in its use.

During this period in which these 286 vaginal hysterectomies were done, with a total mortality of 4 cases, i.e., 0.7 per cent., 435 sub-total and 366 total hysterectomies have been performed with a combined mortality of 7.17 per cent. Such a mortality for abdominal hysterectomy may purchase criticism as compared with the 2 to 3 per cent. mortality of such operations in Great Britain, but it should be remembered that gynæcological surgery is only in its infancy as yet in the tropics and that India is only now entering that era which began in England with Lawson Tait and Spencer Wells.

The great majority of uterine tumours that present themselves, are in patients old, debilitated and grossly anæmic. Indeed at times it needs no little temerity to attempt any operation. With the passing of the purdah system and the growth of education, there can be no question that women will soon seek and demand surgery in the early rather than late stages of disease. It is therefore a safe prophecy that the young and bold gynæcologist has a bright future in the tropics.

Prolapse

Personal experiences are always valuable and therefore I want to say a few words about each of these five cases which I am showing you. They are all cases of prolapse of varying degrees, and my house surgeon has collected them for us because there is no gynæcological condition more common in India. Indeed there is usually a waiting list of 20 to 30 in the out-patient department.

Twenty years' experience has given one a cut-and-dried opinion on this subject and I think if a woman is young and wants more children the Fothergill operation is ideal. If she is middle aged, or desires no more children, the interposition operation, with the ligation of the tubes, is best. If, on the other hand, she is old, the prolapse is complete and there exists no pelvic diaphragm, the best results will be obtained from the Mayo-Ward operation of vaginal hysterectomy.

Very rightly you may enquire the respective merits of these operations from the point of view of the tropics. The Fothergill operation takes time—usually at least an hour—and involves the risk of shock and considerable

bleeding in patients who are already debilitated; moreover occasionally a *B. coli* infection and sloughing of the sutures occurs.

Also there is no gainsaying the fact that I have seen out here patients who have been operated upon in Manchester and other centres, in whom the uterus has remained retroverted and a source of distress. In others, subsequent to the amputation of the cervix sterility has occurred or in the event of conception dystocia has resulted, in a few, necessitating Cæsarean section. Moreover, it is not improbable that the procidentia will recur in the event of future natural delivery.

The interposition operation is very quickly performed, there is no bleeding or shock and, from the point of view of prolapse, provided a posterior colpo-perineorrhaphy is done, it is a radical cure, though perhaps like the Bassini operation for hernia it is not absolutely anatomical.

I have done a great number of these operations, both in private and in hospital, and never yet have I regretted one, though it is freely admitted that should a tumour at any future date form in the uterus removal of this organ would embrace difficulties. These patients can leave hospital in 10 to 12 days, and are astonishingly grateful, for the operation is accompanied by very little after-pain as compared with that of the Fothergill.

The Mayo-Ward operation is usually indicated in old people, and can be performed in under a half hour, which reminds me of a very useful tip that I have been making use of recently, namely, when doing any vaginal operation where bleeding may be expected, if you will inject 1 to 2 c.cm. of pituitrin into the para-cervical tissue before making your incision, there will be almost complete anæmia and hæmostasis.

The Mayo-Ward technique of vaginal hysterectomy is followed up by a posterior colpo-perineorrhaphy, but should the patient be debilitated, this part of the operation can be put off for a few weeks, and be done later under novocain.

What I want to impress upon you to-day is that pessaries have no real place in the treatment of prolapse, and that the operations are easy and should inspire no fear in the hands of a hospital surgeon. Moreover, do not forget that prolapse is a hernia and like other herniæ tends to become larger as the patient grows older and musculo-fascia gets thinner.

Abortion

In these days of economic depression it is impossible to lose sight of the fact that the conscience of the practitioner is becoming more elastic in the matter of abortion. To my mind modern laxity in the observance of the Hippocratic Oath is very regrettable, for our attitude should be a linch-pin of the State.

Unless in consultation with a *bona-fide* physician, we are assured that the health of a woman will suffer, we have no right to lend our ears to sob-stuff, lies or inventions, for remember that loose conduct on our part, although it may substantially increase a practice and enhance a reputation for kindheartedness, carries with it the boomerang of one being labelled a conscienceless petty abortionist. Every gynaecologist must perforce be somewhat of a psychologist, as he becomes involved in the problems of modern married life, with its necessity for continence or contraception. In the tropics this problem is made more acute by poverty and sickness, and the necessity of migration to England or the hills, but these considerations should not weigh with us against the balance of conscience, equity and our oath.

My own opinion is that nature must take its course provided there is no medical reasons against its doing so, but if X desires to have no more children, then with the written consent of her husband there is no reason why she should not have her tubes permanently ligated as a prophylactic measure. This is an easy operation which should be possible for any good gynaecologist to perform from below, *i.e.*, *per vaginam*.

After making a vertical incision down the anterior wall of the vagina, the bladder is pushed up, the utero-vesical peritoncum will then be seen, it is picked up by two pairs of forceps, and made to resemble the frænum of the tongue and is cut with scissors. The anterior surface of the uterus is then grasped with a cat's paw and brought downwards, the tube on one side is caught with a long forceps, pulled down, tied in two places, and cut. The other tube is similarly dealt with. The utero-vesical pouch can then be sutured, and the wound closed, or what I prefer to do is to pass two interrupted catgut sutures through one side of the vaginal flap, transfixing the anterior surface of the uterus low down and enclosing the two leaves of the cut utero-vesical pouch, the sutures emerging on the other vaginal flap. When these two ligatures are tightened, not only is the anterior pouch closed but the uterus is anteponated. The vaginal incision is then sutured with continuous catgut. The patient is allowed out of bed on the fifth day and goes home on the seventh.

This operation is very satisfactory and has no complications. It is important to be sure that the tubes are ligated and cut, and are not mistaken for the round ligament. This mistake cannot be made if the tubes, which have a mesentery and are loose with a free margin, are brought down into the incision for inspection before ligation.

Sometimes, when there is retroversion of the uterus, it is wise to vary the operative procedure by doing a vaginal shortening of the round ligaments either by performing a so-called

anterior Baldy-Webster operation or by suturing each round ligament to the anterior vaginal wall.

Obstetrics

In 1931 I published my personal results of 75 lower-uterine-segment Cæsarean sections which had been performed in the previous 4 years, and I pointed out the supreme advantage of this technique for the type of patient who in this country is seen late in difficult labour. I was able to show that in a consecutive series of such cases the foetal mortality was 13.3, and the maternal mortality—14.6. This latter figure being almost exactly half that of the maternal mortality for craniotomy or the classical Cæsarean in septic cases.

My registrar, Dr. S. C. Mukherjee, informs me that during the last 3 years there have been 5,206 confinements in the Eden Hospital. Out of these there have been 163 Cæsareans with a total maternal mortality of 9 and foetal mortality of 7. The lower-uterine-segment operation was performed on 127 patients with 5 deaths only, *i.e.*, 3.9 per cent., a gladdening figure considering the condition in which a great number of our patients arrive in hospital. In 86 of these operations, the transverse incision of the lower segment was employed. In 31 cases supra-pubic drainage was employed because an offensive liquor amnii indicated it, and in every suspiciously septic case glycerine was injected three times a day through a catheter sutured into the uterus, *i.e.*, to the cervix.

In my previous paper I pleaded for surgeons to adopt this operation in India, because there is very little hæmorrhage and practically no shock. It can be done late in labour; either late in a test labour or when the patient is seen after many examinations have been made, provided the foetal heart sounds are audible and over 100 in rate. There is practically no fear of secondary rupture of the uterine scar, because it is in a non-contractable and retractable portion of the uterus. I trust that these unbiased statistics will advance the vogue of this operation in India, especially in large teaching centres.

Before quitting the subject of Cæsarean section, I should like to make known a clinical discovery of some importance to all obstetricians, namely the extreme advantage of the fundal (McCann) incision for cases of placenta prævia. Our mortality from hæmorrhage before I discovered this was very high, but during the last three years no mother has been lost. This area of the uterus, where fusion of the Mullerian ducts occurs, is practically bloodless and if the assistant firmly controls the lower pole of the uterus in his grasp there is practically no bleeding while the surgeon, with his finger between the uterine wall and the membranes, removes the foetal sack with the placenta intact.

Puerperal Sepsis

Again and again during the last year I have been drumming into my students the advantages of the Hobbs' glycerine treatment, and have pointed out how this technique, not only lessens the grave risks of puerperal sepsis in the tropics, but diminishes the stay of patients in hospital by almost exactly half the number of days—a matter of great importance from an administrative point of view in these times of financial distress.

In order to convince you, my registrar has furnished me with the following data which speak for themselves.

In the five years, 1922–1926, before we adopted the Hobbs' treatment, there were 5,796 confinements. The incidence of puerperal sepsis per mille was 100.95 and there were 46 deaths, i.e., 7.8 per mille.

From 1927 to 1931, when Hobbs' treatment was only occasionally employed, there were 7,061 confinements. The incidence of puerperal sepsis was 122.53 per mille and there were 45 deaths, i.e., 6.5 per mille.

During the whole year of 1932 in which I have been using the glycerine treatment intensively, by this I mean that on the first suspicion of sepsis a catheter is sutured into the uterus, for the injection of glycerine three times a day; there have been 1,940 confinements. The incidence of puerperal sepsis was 109.28 per mille and there were 3 deaths, i.e., 1.54 per mille only.

Moreover during the last 12 months I have entirely given up the use of antistreptococcal serum and substituted injections of Aolan, or skimmed milk. In addition no student, doctor or nurse was allowed to be in attendance on any labour case without a properly-adjusted mask over the nose and mouth. Brilliant green 1 in 100 was the only antiseptic used.

From a tropical point of view it may be that all these factors have combined to give us a record year as regards the paucity of deaths from puerperal sepsis, but my own impression is that the main credit is due to the keen work of my staff and the efficiency of the glycerine treatment, for all of you know the dreadful condition in which large numbers of our patients are brought into hospital after hours in labour and much mishandling.

The moral these statistics clearly demonstrate is one of enormous importance to every doctor and to every woman's hospital in the tropics—namely, that they have in the glycerine treatment and the injection of milk, together with the use of brilliant green and masks, a sure method of combating one of the greatest perils attaching to obstetrics.

My house staff will be very pleased to show any of you with what ease and simplicity a catheter can be inserted and sutured to the cervix of a puerperal patient without pain or fuss.

Most earnestly I beg you to accept the lesson of this method and these statistics.

YAWS IN THE NICOBAR ISLANDS*

By A. J. D'SOUZA

MAJOR, I.M.S.

Senior Medical Officer, Port Blair

INCIDENCE of yaws in the Nicobar islands is not mentioned in standard books on tropical medicine. I have received reports from time to time, since my arrival in Port Blair, that syphilis is very prevalent in the Nicobars, causing severe disfiguration of the inhabitants and threatening the extinction of the race. Two typical cases of yaws in the secondary stage were noticed by me among Nicobarese, who were sent to Port Blair in 1930 for a trial for murder, these were cured with two injections of novarsenobillon (0.6 and 0.9 grammes). This led me to suspect that the cases reported to be suffering from syphilis in the Nicobars might be cases of yaws. I understand that Lieut.-Col. Barker, I.M.S. (1925) reported a case of yaws from the Nicobars, but I fail to find any other record of the prevalence of this disease in the Nicobars. An opportunity occurred for investigation when the census superintendent for the Andaman and Nicobar islands required the services of a sub-assistant surgeon to record anthropological measurements of the Andamanese and Nicobarese in connection with the census report for these islands. Dr. Naidu was deputed for this work and I sent him well equipped with, I considered, an adequate supply of novarsenobillon in the hope of temporarily ameliorating the condition of the people, and awaited a report from him as to any further steps to be taken to combat the disease. I may mention that the Andaman islands are free from yaws, while syphilis and gonorrhoea are common and are principally responsible for undermining the fertility of the aborigines. Dr. Naidu worked under difficult conditions with regard to language, the time limit, and discomfort of a camp life, from 7th February, 1931, to 18th March, 1931. From his report, it would appear that an interesting study of tropical diseases could be made in these islands. The principal diseases prevalent in both the great and little Nicobars are yaws and elephantiasis. Altogether he treated 60 cases of yaws.

He also noticed that at Chowra, out of a total population of about 600, 35 were showing visible signs of elephantiasis. During the course of his whole journey he came across only two cases of syphilis—one contracted at Nancowry and the other at Car Nicobar—both trading centres for the outside world with a floating population of eastern nationals. He had a large out-patients' attendance wherever he camped.

* A résumé of a lecture delivered at the Clinical Society of Port Blair on 13th February, 1932.

The people from different islands appreciated the treatment given and expressed a desire to Mr. Bonington, census superintendent, and to Dr. Naidu that they wanted the whole-time services of a doctor for the island. If a doctor would be appointed for them, Teressa or Comorta would be a suitable central place for a hospital or dispensary. As regards medical facilities for the Nicobars, a doctor, appointed by the Car Nicobar Mission (subsidised by local Government), is stationed at Car Nicobar in charge of a hospital, and a small dispensary in charge of a compounder is established at Nancowry, but there are no amenities for treatment at any of the other islands, and only in fine weather can the inhabitants go to these two centres. Dr. Naidu exhausted his stock of novarsenobillon in treating cases of yaws before he returned. On receiving his report I proceeded to the Nicobars with Dr. Naidu, in April 1931, with a plentiful supply of novarsenobillon. We took the opportunity of examining some of the cases that had received an injection two months previously. The inhabitants were so impressed with the efficacy of the treatment that more cases eagerly sought treatment and another 47 cases were treated.

This number would have been considerably bigger if it had been possible to send information of our impending visit to the various villages. The cases that had received an injection in February or March had all healed up with the exception of two who still manifested latent infection and indolent sores. These were given a second injection.

Yaws (Frambæsia)

Local synonyms for yaws, 'Aiyoke' (Teressa) and 'Aiyak' (Chowra), and for syphilis 'Thannoi' and 'Sakayace'. Although they do not bear any relation to the native names mentioned by Manson or Castellani, there is a resemblance in phonation in the local synonyms in the two islands, while it is noteworthy that the names for syphilis are distinct and definite without any such similarity.

Geographical distribution

The Nicobar islands may be regarded as a continuation of the chains of islands of the Malay archipelago and are adjacent to other endemic area of yaws; viz, Upper Burma, Assam, Siam, Ceylon, Java, and Sumatra.

While it has been observed by authorities on yaws that the disease has a predilection for certain native races, particularly of the negro or negrito stock, it is not known among the Andamanese who belong to the negrito stock, although syphilis is very common among them, and yaws exists endemically within 150 miles of these islands.

Epidemiology

The sanitation is primitive and conditions are ideal for the maintenance of infection. The

people live in primitive huts whose floors and walls may be impregnated with infection. Where human beings, dogs and pigs live huddled together, it is easy to understand how this disease spreads rapidly.

It is quite possible that house infection is important, judging by the habits of the people, but from the innumerable flies we saw settling on yaws sores it is easily conceivable how these convey the spirochaetes to pre-existing breaches of skin of the inhabitants.

The principal occupations of the people are cultivation of cocoanut and tobacco, pig herding, and fishing.

Ætiology

In our series adults were most commonly affected. We could not get information regarding their age, but, guessing from their appearance, it is most common amongst men between 20 and 30 years and amongst women about 25. The youngest patient was 3 years old, and the oldest 45. In our series there were 26 men, 8 women and 4 boys.

As regards the local theory of the causation of the disease, people of Chowra were not able to offer any suggestion, while in Teressa they attributed it to eating papaya fruit; they believe that this is heating to the body, and that the rash thus brought out is aggravated by the itching produced by the bites of mosquitoes and flies.

Causative organisms.—Conditions did not favour extensive laboratory examinations, but we were unable to demonstrate the spirochæte in scrapings from the sores. Wassermann reactions were not done and the diagnosis of cases is entirely based on clinical and therapeutical evidence. We did not come across any case where yaws and syphilis coexisted. Only two cases of secondary syphilis with typical eruptions were seen by us and the eruptions were so distinct from those of secondary yaws that one could not mistake them clinically. As the disease was seen mostly in young adults, no case of endarteritis or arterio-sclerosis was noticed; this however is very rare in yaws, although common in syphilis, and is useful in the differential diagnosis of the two diseases.

Incubation period

No definite information could be obtained from the people at Teressa or Chowra regarding the incubation period. Some of the Chowra people thought that it might be one month. The period is probably a longer one. The source of infection in one patient was traced more or less definitely. A case of yaws from Chowra went to stay with her friends at Nancowry and a woman in whose house she was staying developed yaws three months after the former had left her house and returned to Chowra. No other history of exposure to infection could be traced, so that a period of 92 days given as the maximum in some of the

books appears to correspond in this case. We have of course to take into consideration that their idea of dates is somewhat different from ours.

Primary stage

'Madre Buba or Mother Yaws'. An infiltrated papule develops at the site of inoculation or a granuloma in an old skin lesion, such as an ulcer, an itch pustule, an insect bite, or any abrasion or scratch incidental to a jungle life. In the initial stage, they complained of intense itching, lasting for about a week. It is interesting to compare this with the chronic infective granulomatous condition common on the neck and hump in cattle in Port Blair. In our series, the lower part of the leg was the site of predilection, other common sites being the thighs, arms, buttocks, and groins—all extragenital. No case was seen of primary lesion on the breasts of nursing mothers or mouths of suckling babies, nor in women at the bend of the elbow nor on the hip. The lesion is remarkably persistent lasting even up to a year, or it may heal up in about a week to 2 months time, leaving a white scar (no pigment). If the sore does not heal, it begins to enlarge and in about a week's time from its appearance it begins to ooze a yellowish secretion, with the itching consequent to intense local irritation, or it becomes covered with a thick crust or scab, due to inspissation of the secretion. Constitutional symptoms were negligible in the patients examined and interrogated by us, and the lesions did not incapacitate them from work for any appreciable period. Pain was complained of by patients both at Chowra and Teressa particularly in the early stages, but it disappeared when the yaws was fully matured. Although induration is said not to be the rule, this was noticed in half the cases. Enlargement of the lymphatic glands was not conspicuous and there was not a single case of suppurative glands in any of the three stages.

This stage lasts from few weeks to several months, in our series the average duration was 3 months and the primary lesion was present in most cases with secondary eruptions.

No treatment was adopted by them in the early stage and it was not until the yaws became a large granulating ulcer that treatment by application of leaves was resorted to.

Secondary stage, or stage of generalised eruptions

The onset of this stage corresponds with the decline of constitutional symptoms and most of our cases treated were well advanced in the secondary stage. Generalised eruption is ushered in as follows:—Minute roundish papules of the size of a pin-head are seen, with a yellow crust at the apex, usually three months after the primary lesion, lasting a few weeks and leaving, when they disappear, furfuraceous patches; these patches are circular and show a

fine sand-coloured desquamation as if the skin has been dusted over with flour or *atta*. This condition was only noticed in one of our cases. Some papules coalesce, enlarge, and the skin gets proliferated or hyperkeratoid.

'Keratoid exanthem' of Scobe and Sellard, which is common on the face and limbs persisting throughout the attack of yaws, was not seen in our cases, nor was pigmentation present in any of them. The eruption is very characteristic; from its appearance resembling a raspberry it is called 'frambœsia'. Papules appear around the primary sore. The itching produced by these is intense. Like syphilis, the eruption is pleomorphic, scaly, papular, roscolar or ulcerative, and appears on exposed situations and on the anterior surfaces. The common sites are the legs, forearms, arms, thighs, groins, trunk and face; only one case of scrotal infection was seen. There is no pain and the peculiar offensive sour or musty odour, due to infection with Vincent's bacilli, was absent in our series. Papules appear in regular constellations, large ones being surrounded by satellites. Auto-inoculation is probably responsible for their symmetrical appearance on contiguous areas of skin or mucous membranes, such as the anus, groin, angles of mouth, and vulva. Other characteristics in our series which correspond with the general description in books are that the eruption is painless, mucous membranes and bones are unaffected, there were no eye symptoms, and the patient was able to attend to his work throughout this stage.

No case of 'ringworm' yaws was seen. Not a single case of hyperpigmentation was noticed by us. Only one case of arthritis of the knee was seen, although arthritis of both large and small joints is said to be common.

Periostitis was common, particularly in the digital phalanges. There were no nervous symptoms; hyperhidrosis, a sign confined to hand and soles particularly in children, was not seen.

Tertiary stage

This is a stage of gummatous nodules and deep ulcerative processes. The transition period between secondary and tertiary stages differs widely from that of syphilis. Instead of getting absorbed and healing, yaws may spread marginally, as well as deeply, and lead to extensive ulcers which may last for years. Such ulcers may involve deep structures, producing necrosis of bone or cartilage, or give rise to cicatricial contractures.

Onychia, paronychia, atrophy, and shading of nails were present in a few cases. Multiple dactylitis with uniform swelling of the phalanges was noticed in the case where the tibia, forearm and clavicle were also affected by periostitis.

Yaws on the soles of feet is limited by thick skin. Like an abscess in this region, it is

under high tension. It attains a large size before it bursts and is therefore very painful. When the thick epidermis gives way, this is converted into a fungating ulcer and, although painful to the touch, is not painful to the same degree as it was before it burst through the skin. This ulcer, after the pent-up secretion oozes out, appears like the section of a pomegranate cut through with a knife. In one of our cases this condition had lasted over two years and showed no signs of healing even along the margins, which were thick and indurated. Perhaps want of dressing, and constant irritation from dirt are responsible for the prolonged duration in this case. The lesions were unilateral.

One case of 'clavus' was also seen.

'Gangosa'

This is a destructive, disfiguring process with deep ulceration of the nose and pharynx, and is said to commence as an ulcer of the soft palate. It spreads slowly and leads to complete destruction of the hard palate, the soft parts, cartilage and bones of the nose, in some cases sparing the upper lip which forms a bridge, in other cases leading to its partial destruction. A great cavity is left with the tongue, which remains unaffected, as the floor. Two typical cases of this condition were seen. A third case showed spontaneous arrest—duration about six years. The larynx was unaffected, articulation was seriously impaired, but phonation was retained. There were no other bone lesions in these cases. The age of the three patients was between 35 and 45.

Bone lesions

These are common in the tertiary stage. As in syphilis there are painful nodes on the anterior surfaces of long bones, such as the tibia, radius, ulna and clavicle, which are hard, tender, and painful in the beginning, and remain as thickenings when the acuteness subsides.

The characteristic sabre-shaped deformity of the long bones affecting the tibia, forearms, arms, and clavicle was noticed in one case.

Fibrotic tumours, called juxta-articular nodules, over the olecranon and lower end of the femur, which are painless and multiple were seen only in one case.

Skin lesions

Healing of subcutaneous gummata with loss of pigmentation of skin resulting in leucodermic patches is common and unlike syphilis it is not confined to the hands, ankles, wrists, feet and palms.

General health

In spite of the animistic ideas of the inhabitants, they appear to be grateful for western

methods of treatment and they need no persuasion to be injected, as after the first course of injections given they gain faith as to the efficiency of our method of curing the disease.

They believe that it is a chronic disease, but not a fatal disease. Although at Teressa, many adults are reported to have died of the disease, at Chowra only 3 children under 10 have died from yaws within the last 3 years. We have to take into consideration an outbreak of small-pox which may have been responsible for the large number of deaths reported at Teressa.

Relapses are not common and one attack confers immunity. It has been observed by investigators that 'apparently saturation of a community with yaws virus produces a relative immunity to syphilis' and this may account for the few cases of syphilis seen on these islands.

Treatment

With the limited time at our disposal the only treatment tried was injections of novarsenobillon,

0.9 gramme for adults,

0.6 gramme for young adults,

0.3 gramme for children up to 10 years of age.

One injection appears to have cured most of the cases, although this needs confirmation by a second visit to the islands to examine the cases that have been injected.

Treatment adopted by the Nicobarese

At Chowra, application of certain leaves, *Rafab*, according to them appear to check the disease. At Teressa, the ulcers are rubbed with sand and then washed in sea water; this is supposed to irritate the ulcers and assist cleaning; a paste of leaves (*Ramintho*), made by boiling and grinding, is then applied. Ulcers are said to disappear in a few cases after a series of applications. The inhabitants appear healthy and well nourished, and yaws did not affect their general health, so that the prescription of tonics and good food as general treatment was not necessary in them.

Prophylaxis

It is evident that direct contact is the usual method of transmission of the disease from person to person. According to Manson-Bahr, blood-sucking insects may be responsible, but, in the Nicobars, flies appear to us to be the more likely agents. The local theory of communicability in certain islands is that partaking of contaminated food produces yaws. In my opinion the only way of adopting prophylactic measures for the eradication of the disease is to appoint a medical officer with a steam launch at his disposal for one year, so that he can visit all the islands in turn periodically and give

THE RÔLE OF CHÆTOPODS (SEGMENTED WORMS) IN THEIR RELATION TO MAN

By C. STRICKLAND, M.A., M.D.

Professor of Medical Entomology
and

D. N. ROY, M.B., D.T.M.

*Assistant Professor of Medical Entomology,
School of Tropical Medicine, Calcutta*

(Read before the Indian Science Congress, 1933)

THE Annelid worms comprised within the orders of the Oligochætes (earth-worms) and Polychætes (sea-worms) do not often come within the purview of the medical man or pathologist, although the occasions on which they do so are interesting and sometimes important. It is from the economic point of view that they must be assessed to be of much greater interest to man.

Their economic importance was pointed out of course by Charles Darwin who realised what a vast influence the earth-worms have in the cosmogony of Nature by their uplifting of the soil and amplifying the bounties of plant life to man. Then the aquatic species provide fish with much of their food, for example the Oligochæte Tubifex, which burrows in the soft mud of shallow collections of water, is preyed upon by fish just as are the earth-worms on land by birds, and likewise the Polychætes, or bristle-worms, which live in the sand or slime on the bed of the sea or tidal rivers, provide food for vast numbers of fish, these worms indeed being sometimes used as baits by fishermen. And more directly than this, man sometimes uses these creatures for food; Professor Percy Moore of Pennsylvania University has informed us that he has seen Italians engaged on rail-construction in the United States using earth-worms for making soup, the worms being boiled and the solids then strained off and discarded. They cannot however be considered to have much direct food value to man, otherwise they would not exist in such numbers as they do while poor beggars are rummaging in dustbins for scraps of food. At any rate we are told by Dr. Hutton on the authority of a friend of

(Continued from previous page)

appropriate treatment where necessary. Each endemic area needs to be visited at least once in three months.

In conclusion, I wish to express my thanks to Dr. D. Naidu for his loyal co-operation and help in collecting statistics and local information, and in treating cases under adverse conditions.

his who made a 'practice of experimenting on every sort of animal and insect food' that they are 'uninteresting' to the palate.

While the Chætopods have not yet made their appearance in the pharmacopœias of any 'western system' of medicine one may note that they are made use of in certain other 'systems', and in this connection we cite Gate (1925):—

'Worms are used in various preparations by the native doctors both in Burma and India. In Burma the most important use is in treatment of a disease called "Ye se kun byo", the symptoms of which as described by Burmans greatly suggest pyorrhœa. The worms are prepared by heating in a closed pot until reduced to ashes. The ashes are either used alone as a tooth-powder, or to the ashes are added roasted and pounded tamarind seeds, and unseasoned betel-nuts to make up the powder. This is supposed to be a sure cure for the disease. When attempts have been made to learn which species of worms are used for this medicine, the answer is invariably, "Oh, just the common one found crawling around during the rain".

In a disease called "Mc kha yu" the symptoms of which are white-spots on the tongue and membrane of the mouth, slight fever, laxity of the bowel, and, in very small children, inability to suckle, the remedy is worm-ash applied to the spots in the mouth. It is also used similarly for canker.

A disease called "Kalay yawga", the symptoms of which are vomiting, laxness of bowels, and excessive thirst. For this earth-worm castings are roasted, shaken thoroughly in water, and the clear fluid decanted. Dose—a cupful to be drunk once a day. This is said to be "very cool medicine for hot stomach".

A disease called "Mainma mecphwa noyeekhun thwaykhan". Symptoms are general weakness after pregnancy and inability to nurse the child. The common worms are boiled in water with salt and onions. The clear fluid is decanted and mixed with curry or other food.

A disease called "Panthay ana", the symptoms suggesting impotency. The oil from the bodies of three toadstools is mixed with five ticals weight of sesamum oil. In the mixture three large worms are boiled. The oil is decanted and used to massage the penis. This is said to be "exceedingly powerful medicine".

The earthworm *Lumbricus* is used by quacks in India and in some cases by the Kavirajes as a medicine. It is boiled in pure mustard oil and the preparation applied as an antiseptic to ulcers and sinuses.

The body-juice of fresh *Lumbricus* mixed with fresh raw milk or butter is often widely used for aphthous and ulcerative stomatitis not yielding to other medicines.

Such are the examples of Chætopods in their rôle of utility to man. From the medical standpoint we have a few but interesting records.

From the public health side we have found earth-worms in their early stages appearing in the water-supply of large cities. In one case that came to our notice it was thought that the young worms had migrated through the soil down to the mains and been sucked in to the pipes through a gap in the joints.

On the other hand we have a few reports of Oligochætes 'parasitising' man.

Curling (1839), cited by Blanchard (Blanchard and Savignac, 1910) reported 'worms'

Dactylus aculeatus from the urine of a child. They were thought to be helminths, but the figures given suggested that they were the Oligochaete species *Euchytraeus albidus* Henle.

Waldenstrom in 1873, cited by Blanchard (Blanchard and Savignac, 1910), reported a case in which there was a vaginal discharge, irritation of the pudenda, and the patient complained of violent pains on any movement. After about a year a common earth-worm emerged from the vulva and the pain ceased immediately. Apparently the worm had caused the symptoms; the pain was probably due to the setae, and the creature had lived for such a long period as a 'pseudo-parasite'.

Bergh in 1885, cited by Blanchard (Blanchard and Savignac, 1910), *q.v.*, found *Euchytraeus buchholzi* in the mouth of a patient suffering from weakness, salivation, and vertigo. Possibly this species had been imbibed with well-water. The author thought that after entering the stomach it had later been evacuated into the mouth.

Hanau in 1899, cited also by Blanchard (Blanchard and Savignac, 1910), reported the case of a young woman who affirmed that certain worms which she exhibited had come from a perityphlic fistula of 4 years' standing. They were identified as *Henlea nasuta* and *Microcolex modestus*. But she later confessed to having placed earth around the opening of the fistula 'in order to keep it fresh'.

Delage in 1905, cited again by Blanchard (Blanchard and Savignac, 1910), recovered a specimen of *Allolobophora fætida* from the urine of a patient.

Blanchard and Savignac (1910) gave a detailed account of a case watched for over 4 years in which there was reported nausea and general malaise, simple or bilious vomiting, and indigestion, and in which some worms were discovered by the patient in the vomit. These worms were *Henlea nasuta* and *Friederica bisetosa*, they were always produced dead, and none appeared in the stools. The authors finally concluded that the case was one of neuromimesis.

Heymons (1926), described the passing of *Pachydrius lineatus* on two occasions in one week. He was inclined to disregard the occurrence as accidental until two others came to his notice, leading him to the opinion that the species being very adaptable in its habits might very well come to live in the human intestine.

Müller (1927), later asserted that there was no doubt about this worm's ability to live in the human intestine as he was aware of a case of abdominal trouble which had been relieved when a number of the worms had been passed.

With regard to the Polychæta in relation to pathology we have the following records:—

Biswas and Strickland (1927) described a living polychæte worm of the genus *Nereis*, a mature, active individual about an inch long, which was discharged in muco-pus from the nose of a patient after much coughing and sneezing in the course of an acute and painful attack of coryza due to, or aggravated by, the presence of the worm. Although Nereids are typical marine worms, some of them, like a great diversity of other marine animals, have considerable power of adaptation to the sundry tidal and seasonal variations of deltaic waters, such as the Hooghly at Calcutta. What is remarkable is that the creature should have found its way unnoticed into a man's nasopharynx, and having done so, could have lived there for a week or more.

Dr. Sur, of the Calcutta Medical College, has brought to our notice another worm, which has been kindly identified for us by Mr. Monro of the British Museum as *Nereis (Lycoris) verrilli*, Grube. The specimen was a typical Indian marine species and showed no signs of having been affected by intestinal juices. It lived for about 3 days in tap water and then another 4 days in normal saline, in which it laid a large number of eggs which did not hatch out. It was passed in the stool by an apparently-healthy child about 2 years old. It was detected moving in the child's motion when the mother went to wash it away from the floor of the house where it had been evacuated.

Conclusion

We may conclude by asserting the vastly greater importance of these worms to man from the economic point of view rather than the medical. The comparatively few medical cases that have been reported may be grouped into two classes, firstly those of interest to the psychiatrist, and secondly those to the surgeon or gynæcologist, these being probably all due to contamination of the water in the use of man, the worms adapting themselves to such diverse situations as the vagina, nasopharynx and intestine.

MARCH

SIXTH BRITISH PHARMACOPŒIA (1932)*

MANY years ago it was laid down that the object of a pharmacopœia was to select from among substances which have medicinal power those whose utility is most fully established and best understood, and to form from them preparations in which their powers may be exerted to the greatest advantage. The modern pharmacopœia has, however, become more a book of standards, its fundamental object being to provide standards for drugs and medicines of therapeutic usefulness which have a wide application in medical practice. It lays down tests for the identity, quality, and purity of drugs. That there should be such a standard for drugs intended for the use of physicians is imperative in order to ensure uniformity in their activity and physical properties, to make certain that an article sold under a pharmacopœial name conforms to the pharmacopœial standards, and to provide a basis for the legal control of pharmacopœial substances. It should be realised, however, that in Great Britain the British Pharmacopœia is accepted only as a 'presumptive standard', and is not recognised by legislation, as it is in some of the Dominions. The pharmacopœia is, moreover, the chief safeguard of one of the most time-honoured principles of the medical profession, namely that there must be no secrets about the drugs used in the treatment of disease. The physician must have full knowledge of all the constituents and of all the properties of the drugs he prescribes; there can be no compromise. The physician should always bear in mind that he is the sole judge of what is suitable for his patient.

As a national pharmacopœia is primarily meant to meet the claims and satisfy the needs of physicians of its own particular country and period, there must exist differences not only between pharmacopœias of various countries, but also between various editions of the same pharmacopœia. In almost all countries, therefore, the national pharmacopœias are produced by a recognised authority, and in many directly under the supervision of the State; the noteworthy exceptions to this latter practice are the United States of America and Great Britain.

Attempts have been made to form an international pharmacopœia; in 1925 the second international conference on the unification of the formulæ of powerful medicaments held its sitting in Brussels and drew up a scheme for an international agreement. This agreement was completed in 1930 with the concurrence of the British Government, who, however, rightly reserved the right of introducing modifications in detail in accordance with established usage or the progress of medical and pharmaceutical science. The desirability of maintaining standards on an international basis for powerful and dangerous drugs, especially narcotics, is obvious, but so also are the difficulties in the way of complete internationalization of pharmacopœias. What has been achieved so far on these lines is satisfactory, but we can see great disadvantages in pursuing unification too far, and we consider that each country should evolve a pharmacopœia best suited to its own peculiar climatic and racial factors, with due regard to the raw material available within the country, and without departing from the international standards.

The British Pharmacopœia is produced under the authority of the General Medical Council by the Medical Acts of 1858 and 1862, and the first edition of this work appeared in 1864. Subsequently, several editions have appeared at irregular intervals; the fifth pharmacopœia was published in 1914 and the most recent, the sixth, made its appearance late in 1932, the first copies arriving in India a few months ago. Very considerable credit is due to the pharmacopœia commission, a body of eight distinguished members of the medical and pharmaceutical professions in Great Britain, who after three and a half years of intensive labour produced the new British Pharmacopœia, which in the opinion of many eminent authorities is the most systematic and efficient that has so far appeared. The actual work of preparing various sections was delegated to sub-committees of experts in various branches and they in their turn were advised by pharmacopœia committees in different parts of the British Empire; at the same time close contact was maintained with the corresponding American authority responsible for the revision of the United States Pharmacopœia, which is now already proceeding with its labours for a revised edition due in 1935. In order to keep pace with modern developments the commission has proposed that new editions should henceforth be published regularly at ten years intervals; and it is hoped that in future the British and United States Pharmacopœias will alternate about every five years.

The appearance of this new pharmacopœia is an event of considerable importance, not only to the medical profession but to the profession of pharmacy, as the training and examination of pharmacists are based upon it, and their daily practice is influenced by it.

* *The British Pharmacopœia*, 1932. Published under the direction of the General Council of Medical Education and Registration of the United Kingdom, for the General Medical Council, by Constable & Co., London, 1932. Pp. xlix plus 713. Price 21s. Obtainable from the Oxford University Press and all booksellers.

In preparing the present pharmacopœia the commission has worked on the principle that only those standard articles should be included which are in use throughout the British Empire. Those drugs or substitutes which have a purely local use have been left out with the idea that they will be defined in supplements or *addenda* prepared by the authorities of the countries concerned. It thus comes about that although there are a large number of additions, which was to be expected, there are also an even larger number of omissions. Nevertheless, the book is larger than the 1914 edition; there are 641 pages, excluding the index. More details are given in the monographs than in the previous editions and new tests are introduced. The appendices cover about 150 pages and include various analytical data, and methods for the biological assay of drugs.

In the last pharmacopœia there were numerous instances in which a group of drugs had almost identical therapeutic action; in the new pharmacopœia only one member of the group has been selected for inclusion. The *hypodermic injections* have been omitted altogether, as it is considered preferable that the practitioner should prescribe the dose of the active material, as such. In deference to the 'International Agreement', the *vina* have been excluded, and simple solutions of chemical substances will no longer masquerade under the name *tincture*, e.g., *tincture* of iodine is now *solution* of iodine. The infusions are now known as *fresh infusions*, and *concentrated infusions* have been introduced; the concentrated infusion of *digitalis* is not 'official'. *Oculenta*, ointments for the eye, have been introduced, but amongst the *unguenta* there have been many deletions. Other important additions are toxins and antitoxins, vaccines, sera, gases (oxygen, carbon dioxide, ethylene, nitrous oxide), a vitamin-D preparation, liquor *ergosteralis irradiati*, standardised powdered thyroid, and a host of new and approved chemicals and derivatives. Altogether, one hundred and thirty substances appear for the first time in this edition. On the other hand, sixty-one crude drugs, sixty-eight chemicals, and two hundred and twenty-eight galenicals that appeared in the 1914 edition have been entirely eliminated. The omissions include quite a number of Indian and colonial drugs and preparations, and we feel that the profession in India will note with regret the disappearance of a large number of drugs of Indian origin which were included either in the 1914 edition or in the Indian and colonial *addendum* to the British Pharmacopœia of 1898. A list of the principal omissions in this connection is given below.

Acaciæ cortex, *aconitina* and *tinctura aconitinæ*, *anisi fructus* and *aqua anisi*, *aqua aurantii floris*, *aqua carui*, *aqua fœniculi*, *aqua rosæ* and rose petals, *aurantii cortex indicus*, *belæ fructus*, *extractum belæ liquidum*, *berberis* and *tinctura berberidis*, *betel*, *buteæ gummi* and *buteæ semina*, *cannabis indica*, *tinctura cannabis indicæ* and

extractum cannabis indicæ, *cassiæ fructus*, *catechu nigrum*, *trochiscus catechu* and *pulvis catechu compositum*, *chirata* and *tinctura chiratæ* and *infusum chiratæ*, *cubebæ fructus*, *cucurbita semina preparata*, *tinctura cantharidii*, *cusso*, *daturæ folia* and *tinctura daturæ seminum*, *ispaghula* and *decoctum ispaghulæ*, *embelia*, *gummi indicum*, *jalapæ resina*, *kaladana*, *kaladanæ resina*, *pulvis kaladanæ compositum*, *myrobalanum*, *unguentum myrobalani*, *unguentum myrobalani cum opio*, *oleum ajowan*, *oleum chaulmoogræ*, *picrorhiza*, *pyrethri radix* and *tinctura pyrethri*, *tinctura podophylli* and *podophylli indica*, *syrupus urginæ*, *valerianæ indicæ rhizoma*, and *viburnum*.

Although the majority of the drugs referred to in this list are not universally used in the Empire and are not generally efficacious enough to merit inclusion in the new Pharmacopœia, some of them, such as *cannabis indica*, *datura*, *belæ fructus*, *chirata*, and *kaladana* are bound to be missed by the profession. These drugs are known to be potent and are used not only in India but in the colonies also. Besides these, *berberis* has recently been shown to be extremely useful in the treatment of the oriental sore and an ointment made from it is extensively used in trachoma and certain skin conditions. *Picrorhiza kurroa* contains practically the same active principles as the *Gentian kurro* of the pharmacopœia and can be effectively substituted for the official gentian. *Plantago ovata* (*ispaghula*) seeds have recently become a favourite laxative in the West. In America and France, the seeds are in great demand, and have been claimed to possess therapeutic properties in no way inferior to liquid paraffin preparations, so commonly used in habitual constipation. In India the seeds have been in use for many centuries in the treatment of dysentery and diarrhœa. Apart from these, there are a number of drugs used in the indigenous medicine which have been found effective after careful trials by many authorities. To this category belong *Holarrhena antidysenterica* (*kurchi*) for dysentery, *Taraktogenos kurzii* (*chaulmoogra*) for leprosy, *Saussurea lappa* (*kuth*) for asthma, *Bærrhaavia diffusa* (*punar-nava*) for dropsy, and many others which are extensively used by practitioners. Some of these drugs are of interest to India only, others are universally used. Now that these are no longer recognised as 'official' in the British Pharmacopœia, recognition in some other form appears to us to be essential. The question of the advisability of compiling an Indian Pharmacopœia was considered by the Drugs Enquiry Committee, whose report was issued last year. The evidence before this committee left no room for doubt that India should have an official publication which would record what she recognises as a trustworthy and approved *materia medica* of her own. It was the opinion of that committee that an Indian Pharmacopœia should be prepared on the lines of the British and United States Pharmacopœias; this pharmacopœia should include only drugs of known composition, of definite pharmacological action, and of well-established therapeutic use,

whose toxicity has been fully investigated, and for which the necessary standards for determining a safe maximum dose have been worked out by chemical or biological methods. The work that will have to be done before such a pharmacopœia can be completed will take a considerable amount of time, as the field for investigation is a very wide one and up to the present only a very small percentage of the drugs used in this country have been properly standardised as to their composition and therapeutic activity. In the absence of any scientific information regarding the majority of drugs used in the indigenous systems of medicine and in view of the fact that important pharmacopœial drugs of general interest to the Empire, and growing in India, have not been fully dealt with in the 1932 edition of the Pharmacopœia, our present most pressing need is the preparation of a good Indian *addendum* or supplement in which all the available information concerning the important drugs of Indian origin can be obtained.

On p. 51 of our January issue we reviewed a book on the indigenous drugs of India* written by Lieut.-Colonel R. N. Chopra, I.M.S., who was the chairman of the Drugs Enquiry Committee, referred to above. In this book has been gathered all the information available on the

* *Indigenous Drugs of India*. By Lieut.-Col. R. N. Chopra, M.A., M.D. (Cantab.), I.M.S. Calcutta: The Art Press, 1933. Pp. xxii plus 655. Price, Rs. 15. Obtainable from Thacker's Medical Book Dept., Box No. 54, Calcutta, and all booksellers.

subject of drugs of Indian origin used in the western pharmacopœias and of drugs of all kinds used in the Indian indigenous systems. Amongst the latter there are a number the medicinal value of which has been scientifically established, and there are probably many more which when investigated will be put in this category; included amongst the former are those drugs that we have detailed above as being in the old pharmacopœia, or in the colonial and Indian *addendum*, but excluded from the new pharmacopœia. The information given about these drugs is very complete, and is even more detailed than would be required in a pharmacopœia. This book will constitute a valuable supplement to the British Pharmacopœia for physicians and pharmaceutical chemists practising in India, until such time as the Indian *addendum* to the present pharmacopœia has been prepared, and there is little doubt that when this *addendum* is prepared this book will form a sound basis on which to work.

In conclusion, we will summarize our remarks by saying that the new British Pharmacopœia is in every way a most satisfactory production. We offer no criticism for the policy of excluding a large number of Indian-grown drugs which are mainly used in India, as the intention of the compilers was obvious, namely that India should prepare her own pharmacopœia, or *addendum*. It has now become more essential than ever that as little time as possible should be lost in putting into effect the recommendation of the Drugs Enquiry Committee in this particular connection.

TWENTIETH INDIAN SCIENCE CONGRESS, PATNA, 1933

SECTION OF MEDICAL AND VETERINARY RESEARCH

President:—A. D. STEWART, M.B., F.R.C.S.E.,
D.P.H., D.T.M. & H.

LIEUTENANT-COLONEL, I.M.S.

Presidential Address

SOME REFLECTIONS ON MEDICAL SCIENCE AND PUBLIC HEALTH

GENTLEMEN,

Your choice of President of the Medical and Veterinary Section of the Indian Science Congress this year I interpret as a very genuine appreciation of public health and preventive medicine as a branch of science. I cannot claim any great achievement in the realms of pure research; the greater part of my service has been devoted to practical hygiene and to teaching sanitary science. In choosing a subject for this address, it is natural that I should deal with matters in which I have been particularly interested. Public health and sanitary science, however, cover such a variety of matters that I have thought it better to give some general reflections on medical science and particularly public health work, rather than on any set subject.

In what follows I have given some of the qualities of mind, outlook, and belief which I think should inspire

the medical man and especially the hygienist. It is a high standard but one not unworthy of our calling.

It would here deprecate the division of the science and art of medicine into categories like curative and preventive medicine. Such distinctions have now become artificial and detract from the unity of our science. When we speak of medicine therefore, we mean the science and art of medicine in all its aspects.

The science and art of medicine has three sides: curative medicine, preventive medicine, and thirdly constructive or conservative medicine, which we term hygiene. Some apply themselves mostly either to curative medicine or to preventive medicine, but real constructive medicine or real hygiene is the business of both sets of workers. If we consider the present position in England, we find that preventive medicine is becoming more and more a function of the general practitioner, while health officers are becoming more and more curative in their duties. At present curative medicine must hold the first place, but the ultimate aim is prevention of disease. As Sir George Newman says, 'It is not the event of death which we can escape but the incidence of avoidable invalidity and premature death. It is the enlargement of life and the increase of human capacity, physical and mental, which we seek to ensure'.

I would like to consider shortly with you to-day the place of scientific medicine in human life, and to consider also some qualities and attributes which, as

scientists and medical men, we should have and cultivate.

Medicine was first born of the reaction of the primitive human mind to certain forces and phenomena of nature. It was closely fused in the beginning with religious feelings. This conjunction was for good, in that it recognised the psychological elements in man. It brought man at once in touch with the mysterious; and the mysterious is still the most beautiful thing we can experience, and continues to be the source of all art and science. Mostly, however, and more especially later in the middle ages of Europe, the conjunction with religion and superstition acted as a hindrance; the sanctity of doctrines and dogmas embracing physical phenomena stifled independent speculation, investigation, and experiment, which we know to be the very soul of science. Later, medicine in common with other sciences broke the bounds of doctrine and dogma; experiment and observation replaced philosophical speculation, and with the appreciation of the relationship of structure to function culminating in Harvey's discovery of the circulation of the blood, commenced that wonderful history of experiment, investigation, observation, and discovery with which you are familiar—the names of Leeuwenhoek, Jenner, Pasteur, Koch, Manson, Ross, and Ehrlich are some of the landmarks on a wonderful road along which we still travel. But in this something was wanting—the human note, the closer application of medical knowledge and science for the benefit of mankind in general. It needed the spirit of sympathy, of humanitarianism, to bring medical science into close touch with the every-day life of the masses of the human race, to clothe the bones of science with life. We owe the beginning of this reunion of real religion and medical science mostly to the sympathetic labours of Sir Edwin Chadwick in 1840 on behalf of the working classes in England, and about the same time to the profoundly religious nature and preaching of John Wesley. Of this reunion was born modern public health and preventive medicine; and the spirit that connected Harvey the experimentalist, Chadwick the legislator, and Wesley the humanitarian is that which inspires us still in our work for mankind's advancement. The preventive medicine initiated by Chadwick in 1840 and placed on a sure basis by Simon in 1875 had for its main object the improvement of man's environment. Since then the boundaries of medical science have been tremendously widened. Health is recognised to be something more than reaction of body to surroundings or the mere absence of disease. Man is a personality and an entity, a combination of body, mind, and spirit. These are not really divisible parts of men, however, but merely the results of analysis, it is the indivisible combination that makes up the man. The conceptions of health now envisage the full development of these powers, physical, mental, and spiritual, of which man is possessed. By spiritual we mean here that part of our mind and nature which deals peculiarly with the highest feelings and emotions, with the enjoyment and appreciation of æsthetic, moral, and ethical values. We may say that we have now three aspects of public health—curative, preventive, and perfective—appertaining to body, mind and spirit. It may be that matter, life, and mind are but different stages or levels of the same activity. Matter is the organisation, life the organism, and mind the organiser. The quantum theory has made us familiar with the idea of widely varying states and conditions arising from different quantal distributions of the same fundamental quota of energy. The development of our modern conception of public health is therefore logical—care of the body, the mind, and the spirit. We have in the past concentrated on the body; at the present day we realise more and more the importance of studying the mind. It is probably true that we cannot have a healthy body without a healthy mind. In the last 20 years we have made considerable progress in psychological study. Without pretending to particular knowledge, I think Adler has struck the most helpful note in the development of this side. Man, he says, has three problems set him by the circumstances

and conditions of life on this earth—occupational, social and sexual; how to find an occupation that will enable us to survive under the limitations set by the nature of the earth, how to find a position amongst our fellows that we may co-operate and share the benefits of co-operation; how to accommodate ourselves to the fact that we live in two sexes and that the continuance and furtherance of mankind depends upon our love-life. Readers of Bernard Shaw will remember how in his 'Back to Methuselah' he pictures a human race of great longevity and high (Shavian) intellect, in which the greater part of the period of tutelage up to 20 years, say, is compressed and spent in the egg. Actually the facts seem to be the very opposite. The human race is distinguished by its long period of tutelage and teachability after birth, and in the higher races this period is lengthened in comparison with the most primitive. As man progresses in intellectual ability it is probable that the period of tutelage will also be lengthened. Logically the period during which man should be capable of using his fully developed powers to the fullest advantage should also be prolonged. Hygiene and other euthenic measures have prolonged the average length of life in many countries, but too much importance has perhaps been attached to mere length of years. Expectation of life has meant in too great a degree expectation of bodily life. It must include lengthening of the 'expectation of mental powers' as well; otherwise, the gain will be illusory. The part that medicine along with other sciences will play in the care and development of the spirit is for the future, but it will be more and more closely concerned with man in the development of his higher qualities and aspirations. To quote General Smuts, 'It is here that science ranks with art and religion. In its pursuit of truth, in its vision of order and beauty, it partakes of the quality of both. More and more science is beginning to make a profound æsthetic and religious appeal to thinking people'.

Over 2,500 years ago a Greek poet wrote:—

'Who'er can know
As the long days go
That to live is happy
Hath found his heaven.'

The Greeks, like the Hindus, emphasised certain aspects and attributes of nature, clarifying their thoughts and ideas by the conception of a presiding deity, who in the minds of the common people gradually became anthropomorphosed and an object more of fear and propitiation than a guiding principle. Certain cults in philosophy were thus engendered, each appealing and ministering to one of the many sides of human nature and human feeling, none of them true or complete in itself, but each true and satisfying within its own limits and each part of the larger unknown completeness. The words I have quoted are from a play showing the effect of 'orphyic' philosophy on the human mind. This cult insisted on and emphasised the essential and inherent beauty and sacredness of all life in nature. It is perhaps essentially a philosophy of the present, that here and now is happiness, that our existence in this world is the only thing we shall ever know, and even if it is all that we as individual creatures shall ever know, it should in itself alone be a sufficiency. It is good to be a part of life. Life only knows that it is living; it can never know that it is dead. Mortality of human mind and body in this outlook need not be regarded as any impediment to appreciation of the highest beauty in nature.

As Mimnermus said:—

'All beauteous things for which we live
By laws of time and space decay
But oh, the very reason why
I clasp them, is because they die.'

I cannot quite fully understand those who say that they can see no meaning in human life if it is mortal, if this life after death is not to be followed by an eternal hereafter. This seems a policy of despair and disappointment, a confession of lack of appreciation of

the wonders of nature revealed daily to our senses and to our higher faculties.

Dissatisfaction with existence is the result of individual or collective disappointment—a disappointment to which disease has in the past been largely the cause. National fatalism has been bred of epidemic disease. When mankind has banished or controlled disease and lives the normal span of biological existence, the individual should no longer look on death as a spoil sport but as a natural phenomenon. The desire for immortality will not be so insistent. It is a mistake to regard death itself as an evil. In the fullness of years, it is as natural an event as birth. Goethe wrote very truly. 'The spectacle of nature is always new for she is always renewing the spectators. Life is her most exquisite invention, and death her expert contrivance to get plenty of life'. The only real objection is to premature death, so distressingly common.

These ideas have attracted me for many years—that in mortal human life and existence, physical and mental, we have now nature's highest achievement, that, so far as we can see, it is nature's purpose that human life has, or should have within itself, the possibilities of complete satisfaction and happiness; that the preservation of human life, the protection and betterment of the human germ plasm, the mitigation and ultimate removal of the hindrances that beset the path or what we take to be the path of man's biological development and fulfilment, must be fundamentally correct objects of work in life, which should bring satisfaction and inspiration to the worker and benefit to his fellowmen. These aims are in large measure those of preventive medicine, and it is to those who are devoting their lives and energies to this work that I would speak with hope and encouragement. The care and preservation and improvement of human life form one of the highest ideals of work.

The thinking man at some period of his life puts to himself or has thrust on him questionings of the purpose of life, and on his own answer to himself depends his outlook on life, his career, the ordering of his actions, and his life and his relations to his fellowmen, and his bequest to posterity. There are many answers; wealth, power, happiness, peace, security, service, the avoidance of the disturbing and the distressing; and the resultant of these in the intellectual and thinking portion of a nation determine its character and its progress.

In common with many, my own conviction is that in the quest and appreciation of truth and beauty in their largest sense and meaning, lie the best answer to life's purpose, the one that gives the greatest satisfaction. Einstein says, 'To ponder interminably over the reason for one's own existence or the meaning of life in general seems from an objective point of view to be mere folly; and yet every one has ideals by which he guides his aspirations and judgement. The ideals which have always shone before me and filled me with the joy of living are goodness, beauty, and truth'.

Religion and philosophy we would expect to give us helpful and definite answers to our important questionings. Formal religion however by its insistence on human immortality and a 'soul' entity and on formality of ritual and dogma has failed to satisfy the needs of modern thinking man, while philosophy has guarded itself round with too many abstractions to come into every-day life. For the pursuit of truth we look to science, but it is the poet who helps us most in our appreciation and search of the beautiful. It is not surprising therefore that our profession of medicine has enriched the world in art, sculpture, and poetry, and two of them, John Keats and Robert Bridges, have given us perhaps the most notable contributions in the English language, exemplifying the eternal principle of truth and beauty in life. Keats, the consumptive medical student who died at 26, should be one of the most valuable possessions of the doctor. In spite of the shortness, the sadness, and the tragedy of his life, Keats was able to proclaim that beauty at any rate is real and lasting and that a belief in beauty is the one thing needful in life. 'A thing of beauty is a joy for ever'

is an expression that has almost passed into our every-day life. He held that beauty was the strength which always conquered. He was no sentimentalist—no one ever looked fate straighter in the face than Keats.

.....'For to bear all naked truths,
And to envisage circumstance all calm,
That is the top of sovereignty.'

'Beauty is truth, truth beauty' he wrote and in the essentially mutual identity of the two, lies the unity of science and art, the bridge which joins and unifies intellect and emotion, mind and spirit.

Bridges was a qualified doctor who lived a full life, and at the age of 86 wrote 'The Testament of Beauty'. In this he recounts the conclusions of a lifetime of industry and creation. Man's happiness, he tells us, is his living response to the wealth of nature. Beauty is the prime motive of all his excellence.

Life seems so full of contrasts and antagonistic elements. With nature so inexhaustible of beauty, why is there so much of ugliness; with so much that is noble and fine in civilisation, why is there still so much misery, want, disease, and vice?

We know now that what we call matter is a state of harmony between two essentially different but mutually attractive states—the proton and the electron. The study of the atom shows us that the essence of ultimate structure in nature is the existence of opposites—opposites of like and unlike, of repulsion and attraction which acting together produce equilibrium, create cosmos out of chaos, and harmony out of disorder in obedience to law. In life and civilisation we have similarly states, impulses, motives which though essentially of the same class are nevertheless of the opposite sign as we might say. We have for instance on the one hand the instinct of self-preservation in the individual, a complete selfishness in many ways; and on the other, love, self-abnegation, and sacrifice; in civilised life we still have the fierce competition for existence which leads to intense nationalism, jealousies, tariffs, and wars, and on the other hand, there is a growing feeling of the unity of the human race. Nature shows how matter and life itself are harmonious adjustments of opposite entities; in the study of constitution and behaviour of the atom there is probably much we can learn of application to the larger aspects of life, individual, social, political, and international. Bridges tells us:—

'Love from whom the world begun
Hath the secret of the sun
Love can tell and love alone
Whence the million stars were strewn
Why each atom knows its own
How in spite of woe and death
Gay is life and sweet is breath.'

Symbiosis and parasitism are two natural processes which have immense significance for the public health worker. They have been confused in the past but are really definitely different conceptions. By symbiosis we mean the interdependence of all forms of organic life; by parasitism is meant the absolute dependence of one species on another. In symbiosis we have the basis of mutual assistance and development, and evolutionary progress. It leads to mutual aid and has within it the elements of ethical qualities of sociability and communal life, which lead on to the higher ethical and intellectual developments of man, to sympathy, fidelity, and courage. True symbiosis is beautiful; one has but to instance the diversity of flowers as an example. In parasitism on the other hand we see a degrading influence and a danger of injury, disease, and possible death to the host. There is degeneration and decay in structure and form of the parasite instead of progress. It is a departure from healthy competitive evolution which demands from every organism effort, work, self-dependence, and mutual exchange of service.

Parasitism is sometimes defended by biologists as being an integral part of nature, and one often hears of public health work being considered wrong because it is said to be biologically opposed to nature and an interference with some of her methods. Parasitism is

obviously immoral and a lapse on the part of some of nature's products from her higher and better methods. Parasitism is associated with all that is wrong and unhygienic in conduct, both for the individual and society. Immorality cannot seriously be defended as a legitimate expression of natural instincts. Parasitism is one of the chief, if not the chief obstacle in man's onward progress, and the reduction and final obliteration of human parasites in India will be for some time the main tasks of the public health worker. Tolerance of parasitism by a community or by biologists is an acquiescence in a policy of ignorance and dangerous degradation, if not actually an encouragement of immortality in nature.

At the same time one cannot deny that these degenerated types are just as successful products of adaptation and evolution as are what we call the higher types. In fact evolution has tended more often in the direction of what we call degeneration than in upward progress. If, as I think we must, we accept mind as represented in the human being, as essentially a product of evolution, we see how it may be possible for man to control his own evolution to some extent. In this he is unique. What form of control this will or may take, it is impossible now to say for it would appear unlikely that mind has played any important part in guiding evolution up to the present. Eugenics and population control in a wide sense suggest themselves but as Haldane points out we have been accumulating the knowledge necessary for the guidance of our evolution only for a single generation. Modern studies of heredity and genetics have revealed the extraordinary part played by the 'genes' which make up the structure of the chromosomes of the reproductive male and female cells. Chance mutations in the 'genes' produce changes in inheritable characters. Such changes when useful become permanent by natural selection. Biologists have now succeeded in producing changes in inheritable characters by physical and chemical means. The most remarkable experiments in altering the character of the 'genes' in the reproductive chromosomes are those of Harrison and Muller. The former by feeding ordinary light-coloured moths with chemicals was able to alter the pigment gene so that a true breed of black moth was obtained. Muller by X-rays and radium emanations changed fundamentally the 'genes' of the fruit fly in various ways, so that inheritable and permanent mutations were obtained. The suggestions of such experiments are far reaching. The power to change characteristics permanently is apparently a fact, but the changes cannot at present be foreseen or chosen. When man discovers how to change his characteristics in a desirable direction, he will become a master of evolution and produce human beings with finer minds and bodies who will be able to accelerate these first advances towards the human control of evolutionary destiny. Such control, if it is ever possible, is for the very distant future. At present, such ideas are mere speculations, and for many years to come it would appear that the evolutionary possibilities of man will depend on the same factors as for other species, namely, the plasticity of his germ-plasm and environmental pressure; in other words on chance recombinations and new mutations of the genes of the reproductive chromosomes, and on a modified natural selection. In the meantime, the abolition of parasitism is one at any rate of our immediate tasks.

The instinct and desire for truth and beauty is no sentimental idea which lies only in the domain of artists and poets. It is true that the poet and the artist can best interpret beauty and show it to the ordinary man, but it is really the dominant note in all our lives. The child instinctively seeks it, it fills completely the vision of the adolescent, it dominates the selection of the mate, and guides the parent in the teaching of his children, it is the surest rock of satisfaction and contentment to the middle-aged and the old. Its seeking and its attainment give us true 'culture', give life a meaning, an object, a sense of achievement and satisfaction. Without it and without the sense of its

ultimate reality and importance, many human lives are dull, meaningless, and materialistic, and many human beings disappointed and discontented. As one of our leading psychologists says: 'This search for beauty is not a meaningless search. Our æsthetic emotions are always based on a feeling for health and for the improvement of mankind. All our functions, all our abilities, are formed in this direction. We cannot escape it. We know as beautiful those things which look towards eternity, those things which are for the benefit of mankind and for the future of mankind, the symbols of the way in which we wish our children to develop. This is the beauty which is always drawing us.'

Our profession has very great advantages denied to most others—it leads us to the study of nature and man. The study of nature takes us straight to the spring of all knowledge and life; the study of man leads us to consider nature's highest achievement, a study to which we are devoting the best part of our lives. We should look at nature, not as something that provides us with a little chemistry and botany and physics but as the author of our universe, our earth, our race, and our lives. We should regard man not so much as an individual but as an integral part of nature, an interpretation of her highest motive, as a link in a chain of supreme design. Everything in nature will thus become

..... 'Symbols divine

And manifestations of that beauteous life
Diffused unseen throughout eternal space.'

The capacity and desire for the study of nature and man are themselves the reward of thoughtful life—we feel more clearly our relationship to life and nature, for the mystery of man is probably the mystery of nature.

Wordsworth's lines are familiar but can bear repetition:—

'I have learned to look on nature not as in the hour
Of thoughtless youth, but hearing oftentimes
The still sad music of humanity
Not harsh nor grating.....and I have felt
A presence that disturbs me with the joy
Of elevated thoughts, a sense sublime
Of something far more deeply interfused
Whose dwelling is the light of setting suns
And the round ocean and the living air
And the blue sky, and in the mind of man.'
..... 'Nature never did betray—
The heart that loved her; 'tis her privilege
Through all the years of this our life, to lead
From joy to joy, for she can so inform
The mind that is within us, so impress
With greatness and with beauty, and so feed
With lofty thoughts, that neither evil tongues
Rash judgements, nor the sneers of selfish men
Nor greetings where no kindness is, nor all
The dreary intercourse of daily life,
Shall e'er prevail against us, or disturb
Our cheerful faith, that all which we behold
Is full of blessings.'

Planck, the celebrated physicist, considers that the study of nature fosters the two noblest impulses of the human mind—enthusiasm and reverence.

Our instinct for truth and beauty sends us to nature, and one of our strongest responses to nature is to make us listen to the 'still sad music of humanity', to awake our sense of pity with human aspirations, human suffering, and human needs. Pity is one of the strongest forces behind public health work and preventive medicine, and without it the hygienist and his work will be dull and mechanical. Pity should not stop at sympathetic contemplation, but be translated into vigorous action. In the hygienist the spirit of pity for mankind must be exalted into a moving principle. It is the mainspring of public health energy, and the well of our enthusiasm. It is the force that battles against the strong, against conventional sanctions and accepted gods, against the tyrannies of custom and prejudice. It was the driving force within the new humanitarianism of the 19th century, the force that in the hands of Wesley and Chadwick broke the selfishness and the

indifference of the educated classes of England in the early days of the 19th century. Pity was thus the corner-stone of man's collective health, the structure laid so securely by these two pioneers. It has however the defects of its qualities. 'Pity is of its nature combative, it may outrun discretion and reason, and have an unreasoning contempt for consequences, and counting of costs. It may engender a spirit of recklessness, impatience of opposition, and even fanaticism and ruthlessness.' The hygienist must keep the golden mean if he can, but better sometimes a little recklessness than a placid acquiescence in opposing circumstances.

Of the very essence of pity are bred unselfishness and sacrifice, and in the hygienist these are essential qualities. Without them he will be a disappointed man, his work will lose sanctity and grace, become mechanical, and often ill done or scamped. From them however comes the satisfaction of good work well and faithfully performed in obscure places; for the material rewards of public health work are small, and reputation and fame come to few.

The life of a medical man, general practitioner or hygienist, is essentially one of curiosity. We spend our days finding out things and passing judgement on them, and translating our reasonings into actions, ordinary though the latter may be. In some the instinct of curiosity is highly developed and the search for truth becomes a passion and a purpose. We may be all research workers in a sense but it is only very few of us who have the flair and aptitude for original work. The real research worker is one of the most valuable assets of the medical community and should be encouraged in every way.

Research is not a mere matter of knowledge, nor necessarily of industry, and its results cannot be bought. It cannot be produced by any human machinery however industrious and deserving. It is like poetry; many may write rhymes but few have the real gift of poetical feeling and expression. Shelley said, 'A man cannot say "I will compose poetry"'. The greatest poet even cannot say it for the mind in creation is as a fading coal, which some invisible force like an instant wind, awakens to transitory brightness'. So with research—it needs the natural urge and aptitude, it needs the long apprenticeship in technique and art, untiring industry, the highest self-criticism, but above all, it needs the passion for beauty, the living coal which can be made to glow and produce the golden ore. 'Some have digged deep, yet glanced by the Royal Vein, and a man may come into the pericardium but not the heart of truth.' How many of us who undertake research have the necessary qualities, the divine afflatus? Very few we must honestly admit and perhaps there are too many of us who dabble at it; it might be better if we left the real work to the favoured few, but the dominant instinct of creation is so strong in us that we cannot deny ourselves the joy of producing even a little thing of our very own—'a poor thing but mine own'. The joy of creation is akin to that of the poet. Bridges wrote:—

'I love all beauteous things
I seek and adore them
God hath no better praise
And man in his hasty days
Is honoured for them.
I too will something make
And joy in the making
Altho' to-morrow it seem
Like the empty words of a dream
Remembered on waking.'

This is the true spirit of the research worker.

Another quality the public health worker needs, and needs always is courage; courage that is born of belief and faith in one's work, of a life spent in the study of nature and in the quest of truth and beauty. We need it always for there is sometimes a sense of discouragement if not of actual disapproval in the atmosphere of our work. It is strange that this should be so but it

is a factor to be definitely reckoned on in public health work. Let me remind you again that in the development of public health there have been two distinct ideas. Earlier pioneers like Chadwick and Simon placed the improvement of man's environment as the first essential to his health—and they were then right; but further knowledge proved it was not the only essential. Bacteriology showed that environment though very important in its influence on bodily and mental development, was only the vehicle of disease; it passed on microbial disease from man to man; man was in most instances the host and reservoir of his own diseases. The study of man was the next step. Ignorance, bad habits in old and young, faulty nutrition, etc., could engender disease and ill-health in the best of environments. Education, guidance, and more co-operation between the public and the medical profession are some of the modern trends of public health. These clearly demand something from the ordinary human individual—things which he cannot buy and which cannot be gifted to him. Thus the indifference and sometimes active opposition of the individual adds to the task of the modern hygienist. There is a difference of opinion at present as to how far it is justifiable in these matters to interfere with the liberty of the individual. We can point to instances where compulsory vaccination banished smallpox, but there is the example of the U. S. A. and prohibition to show us that public morality by compulsion in one direction may lead to definite dangers in another. To take the case of India—vaccination is compulsory only in about 7 per cent. of the population; but there is considerable evidence to show that vaccination is as well carried out in those areas where it is voluntary as where it is compulsory; and smallpox has since 1880 been reduced in mortality from 2.12 per 1,000 to about 0.16 per 1,000 all over India. There is a growing feeling at present that in public health policy too much compulsion is undesirable and should be kept rather for times of emergency and extraordinary danger. Indifference, ignorance, and conservatism on the part of the individual are definite handicaps to the health worker; so is the idea that health is the affair of the sanitarian only and not the personal business of the community.

There is another line of criticism which appears particularly in times of stress. I refer to what is familiarly known as the 'population problem'. It is stated that in many countries and in India in particular the population has increased and is still increasing at a rate beyond its means of adequate sustenance. Consequently and inevitably, economic stress, unemployment, malnutrition, and disease, if not worse things must ensue. Unfortunately discussions on this problem have very seldom been free from religious bias, from prejudice and sentiment, and from personal, professional, and class interest. Distinguished scientists, astronomers, and clergymen, and in particular biologists have too often used the prestige of their profession and their own personal distinction to weight their arguments. Granted the truth of these, the remedies suggested have often been hasty, superficial, and class-selfish. Some would lightly welcome disasters like floods and widespread epidemics amongst the general masses; but these need not be taken too literally. Limitations of public health work, especially child welfare work, and the wide adoption of methods of birth control are common and serious suggestions that have been made. The subject is so important that I think a free and honest discussion on the following lines would help greatly:—

(1) What evidence is there that numbers alone are the cause of general economic stress. Is it possible to determine when sufficiency of population passes into over-population? We might bear in mind for instance that in England human life has now been rendered increasingly tolerable to a population rising to 40 millions in an island where a century ago 14 millions had found it hard to earn a livelihood.

(2) How far have methods of population restriction alone been the cause of population adjustments?

(3) Is it desirable that the State give facilities for instruction to the general population in methods of birth control (a) for purely medical reasons in special cases, (b) for economic reasons generally? If desirable, are these feasible?

(4) What would be the effect of attempts at such a movement as the latter on the rural masses of India?

On many of these I have an open mind, but when I consider what humanitarianism and science working together have done for human welfare, I cannot believe that to discourage or curtail medical and public health work at any point—antenatal, natal, in infancy, in childhood, or in adult life can in any way be right.

I may be permitted to make one or two general observations on the subject.

Life of all sorts has been and always will be competitive. The population problem in some form or other will always be with mankind. Methods of prudence come with education, with a rise in the standard of living and a heightened sense of responsibility, and there is a considerable amount of evidence that such methods have now begun to be used extensively in the middle classes of India. Those who strongly advocate the wide adoption of such measures are probably activated by a sense of apprehension of personal or class calamity owing to increasing numbers of the so-called lower classes or races, and by a desire for personal, class, and race security. This apprehension and this desire are psychological phenomena much commoner in the educated middle-aged adult than in youth or in the more elementary human masses. The desire for security is a manifestation of the instinct of self-preservation; it is not however an attribute of youth but of middle age, and may be a danger and a hindrance to real progress of the race and detract from the zest of life. Is our present civilisation getting middle-aged, and are its communities seeking for security in every possible way?

After all, the things desirable for happiness in the ordinary man are simple—food, shelter, health, love, and work. 'Courage, hazard, and hardship and sacrifice can give a quality to human happiness undreamed of by those who sit secure in Zion.' Those who put too great a value on security may have to make way for those who do not. The old Titan gods were displaced by a younger race of gods more adventurous than they:—

'So on our heels a fresh perfection treads
A power more strong in beauty, born of us
And fated to excel us, as we pass
In glory that old darkness.'

We should remember that our stability is but balance, and conduct lies in masterful administration of the unforeseen.

I have indicated in some way what I consider should be the attitude of the medical man and specially the practitioner of preventive medicine towards his science and his work. A constant desire for truth; an appreciation of the beautiful, and of the essential reality and unity of these two; a spirit of sympathy and pity for the human race; continuous assiduity in the alleviation and prevention of disease; a belief in the possibility of upward progress of mankind through evolution controlled by intelligence, and in the application of the ideals of preventive and constructive medicine in the development of man's higher attributes; a spirit of conviction and courage in the face of difficulties.

In conclusion, gentlemen, I would remind you that we meet here with the intention of mutual benefit, of giving the results of original work, of original ideas, of presenting problems, of asking for and helping in giving indications for progress.

'What cheers us most is still the cry
Of those who look for larger sky
And find with every cloud withdrawn
Fresh promise of an ampler dawn.'

Only the best and most talented and industrious of us can push aside the clouds, but all of us can keep on looking and learning. Medical life is surely therefore one of the best and most satisfying and interesting. One of the great attractions of science is that it is limitless and will probably always be somewhat of a mystery.

'Remember that in that inner world to which great literature, science, and art belong, a man may go on all his life learning to see, but he can never see all that is there, he can only hope to see deeper and deeper, more and more, and as he sees, to understand and to love.' In this spirit, gentlemen, I commend to you the science and art of our profession and specially the meetings of our own section of Medical and Veterinary Research.

ALVARENGA PRIZE OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA

THE College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about three hundred dollars, will be made on 14th July, 1933, provided that an essay deemed by the committee of award to be worthy of the prize shall have been offered.

An essay intended for competition may be upon any subject in medicine, but must be accompanied by a written assurance from the author that it has not appeared previously in print, either in whole or in part, in any form, and has not been presented elsewhere in competition for a prize. The essay must represent an addition to the knowledge and understanding of the subject based either upon original or literary research. It must be type-written, and in English acceptable for publication without necessity for editing by the committee. Any illustrations should be appropriate and correctly annotated with the text. Essays must be received by the secretary of the College on or before 1st May, 1933.

Each essay must be sent *without signature*, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and, within, the name and address of the author.

It is a condition of competition that the successful essay or a copy of it shall remain in possession of the College; and that it may be published by the author with the consent of the College; other essays will be returned upon application within three months after the award.

No award was made for the Alvarenga prize for 1931.

TRAINING IN RADIUM THERAPY

Two clinical assistantships (unsalaried) are available from time to time at the Holt Radium Institute, Manchester. Appointees (male or female) will be expected to remain for a period of not less than four months on a whole-time basis. Appointees will be required to take part in the routine work of the Institute and will receive a practical training and considerable experience in all aspects of radium therapy. The Institute controls three and a half grammes of radium, and has a whole-time trained medical staff.

Candidates must have had either previous surgical experience or a diploma in radiology. Applications should be made to the Director.

TANUKU MEDICAL ASSOCIATION

THE last meeting of the Tanuku Medical Association for the year 1932 was held on Sunday, the 4th December, with Dr. G. Siva Ram, M.B. & B.S., in the chair. The Association placed on record its deep regret on the premature demise of Rao Saheb Dr. M. Seshadri Reddi, L.M.S., who was one of its members, and also resolved to communicate the same to the members of the bereaved family.

Dr. Ch. Sathivasu, M.B. & C.M., M.R.C.S., and Dr. Y. Suryanarayana Rao, L.M.P., were unanimously elected president and secretary of the Association, respectively, for the year 1933.

Dr. G. Siva Ram gave an interesting discourse on the principles of the Ayurvedic system of medicine, which was followed by some discussion.

THE INTERNATIONAL ASSOCIATION OF HOSPITAL SPECIALISTS

THE International Hospital Association organized from the end of September to the beginning of October of last year a series of international post-graduate courses on hospital technique at the Frankfurt a.M., Municipal Hospital, attracting a large attendance of superintendents, physicians, matrons, architects and engineers, coming from 17 different countries. More than 30 internationally-known specialists delivered lectures on important problems; lively discussions followed.

The lectures on kitchen management, hospital linen and laundry have been published—together with interesting articles by other authors—in the October issue of *Nosokomeion*, the official organ of the International Hospital Association.

From June 28th to July 3rd, 1933, the Third International Hospital Congress will meet at Knocke s/Mer, on the Belgian coast. The study committees of the International Hospital Association will submit their reports to the Congress. The discussions will enable the Congress to draw the outlines of practical conclusions having an international value. A five-day study trip to the Netherlands will follow the Congress.

FIFTY YEARS AGO

(From the *Indian Medical Gazette*, March 1883)

THE views regarding the etiology (of enteric fever) more generally accepted in Europe are as follows:—Some organic or animal, especially faecal, contamination of the air or water is looked upon as an essential factor, but the poison is regarded as of a specific nature, and even capable of imparting its character to other faecal matter.

It is not at all necessary, however, to resort to such a view when we recollect the time during which patients are ill, the number and bulk of the stools passed daily (every particle acknowledged to be capable of exciting the disease in others) and the frequency with which these are allowed to pass into the water consumed by others.

It is true that all the outbreaks of this disease in England have been attended by foul health conditions, such as bad water-supply, absence of drainage, or soakage of sewage from cesspools into wells and the like; not unnaturally therefore there has been a tendency to attribute a prime importance to these conditions in the spread, and possibly also in the origin of this disease; and decomposing sewage has been held to be even capable of generating the enteric poison under certain conditions. A community may, however, go on drinking sewage-contaminated water for years, as pointed out by Dr. Ballard in the instance of the village of Nunmay (Somerset), and only suffer from enteric fever when the disease is imported by a patient suffering from the disease. This shows that something of a specific nature, in England at any rate, is necessary to give rise to the disease.

The history of enteric fever is wholly inexplicable on the pythogenic theory of Murchison, but is decidedly that of a specific disease propagating itself by a specific poison generated in the system. The general belief, is that the disease always arises from its introduction into the locality by a person suffering from enteric fever, and probably in England this is generally the case, for the most common type is the epidemic variety, or true enteric fever.

Cases occur in India where no personal communication has arisen with any one suffering from enteric disease, no sanitary defects are discoverable, the dry earth system works well, the surface drainage is good, and so on. This happens not seldom but very frequently, and is in India the rule rather than the exception.

Troops going out to India don't suffer on the march or voyage out, only in April or May following their arrival; if they arrive in October it is absurd to suppose it is dormant all that time, and it is, moreover, impossible that this should be the case with every corps. Importation then is practically out of the question here.

The causes generally assigned as generating enteric and other fevers are completely inadequate to explain the outbreaks in India. Filth, imperfect sewage removal, and decomposing organic matter are ever present in many places in India, and perhaps also in many other countries, but although the filth is permanent, the disease said to be caused by it is not so; and people live and thrive in the midst of it for years perhaps, without ever a case occurring. This I should think was sufficient to prove that something more than filth was necessary for its production, and if the disease was once introduced how should it disappear until all this filth was removed.

This is one great fact not easy to get over in the theory of the septic origin of fevers; something specific is necessary.

Current Topics

Enuresis Among School Children

By R. J. BATTY, M.B., B.Sc., D.P.H.

(Abstracted from the *Medical Officer*, Vol. XLVIII, No. 13, 24th Sept., 1932)

ENURESIS is a fairly common complaint among school children, and it is a source of considerable worry both to the teacher and the parents of the patient. In some Lancashire schools more than 5 per cent. of the children are affected with this complaint, which is sometimes regarded as so trivial that the mother is told not to worry as the child will grow out of it. Unfortunately this prognosis is justified in only a small percentage of cases which remain untreated, and I was impressed by the large number of cases where the complaint had been established for a number of years. Not infrequently it persists into adult life and seriously restricts the adolescent's chances of employment.

Treatment.—Education is of the utmost importance; everything else is only auxiliary treatment.

The usual methods of education—to teach the child to empty its bladder at meal times, at playtime, before going to bed and also immediately it awakens—are too well known to need further elaboration. But the child should also be awakened for urination about 10 P.M. each night, and also as soon as the parents rise each morning. The important point is that this training should start quite early in the life of the infant—certainly not later than the first year.

Before any specific drug treatment is started, all co-existing defects should be put right if possible. In 21 cases I was able to get the patients to undergo an operation for removal of tonsils and adenoids, and in seven cases this measure alone cured the bed-wetting. This gives an operative cure rate of only 33 per cent., but the proportion compares favourably with the results obtained by the usual popular remedies.

Of drug treatment, anthelmintics form the most successful remedy. Threadworms are a prolific cause of bed-wetting, and it is impossible to cure enuresis in such patients until the worms have been eradicated. I

have found Butolan (Bayer), i.e., P-oxy-diphenyl-methane-carbaminate, the most effective anthelmintic. It is put up in the form of $7\frac{1}{2}$ grain tablets. Half a tablet three times a day after meals is sufficient for most children and results in copious evacuations of thread-worms in the stools. It should be combined with a simple purge given every other night and followed by a saline enema the next morning. Frequently it will be found that the whole family is infected with worms, although only the one patient has enuresis as well. Hence, every member of the family should have the stools examined for the presence of worms and treatment must be carried out where necessary. Failure to do this will only lead to eventual disappointment at frequent relapses in the original enuretic patient in the family, through re-infection with worms.

During the past hundred years, belladonna has had the reputation of being a specific in enuresis. The usual advice given is to push the dosage until the child is on the verge of belladonna poisoning. Such treatment, however, only makes the misery of the little bed-wetter more acute. A child with dilated pupils cannot study and will have an unhappy time at school while undergoing intensive belladonna treatment. Further, if any co-existing defects (worms, for example) have not been put right a relapse into bed-wetting is certain as soon as the belladonna is withdrawn. Moderate doses of belladonna act equally well, in my experience, if given over a prolonged period in purely functional cases without co-existing defects.

Space does not admit of a description of every other drug which has been tried.

With regard to psycho-therapeutic methods, simple suggestion acts best of all when removal of co-existing defects has failed to cure. It is the quickest and cheapest of all methods of treatment. The results are usually dramatic, and the gratitude of the parent is correspondingly great.

The Domestic Treatment of Insomnia

By LEONARD WILLIAMS, M.D.

(From the *Medical Press and Circular*, New Series, Vol. CXXXIV, No. 4876, 19th October, 1932, p. 312)

IN furtherance of the endeavour to cultivate therapeutic common sense, to which I have devoted a good deal of my professional life, I have on more than one occasion made so bold as to indulge in the generalisation that the problem of sleeplessness may be reduced to a mathematical equation, thus: insomnia = dyspepsia. When, as in such a case, an attempt is made to explain a condition which is no more than a symptom, by praying in aid another mere symptom, the situation would seem to demand a good many saving clauses and footnotes. I do not propose to indulge in any such, feeling that vagueness is nowhere more permissible than when considering matters connected with sleep, a phenomenon about which nothing is really known.

The type of dyspepsia which is most provocative of insomnia is certainly the hyper-acid or sthenic type. And this is what usually happens: the patient goes to sleep normally, but is painlessly, but widely awakened about 4 A.M., after which sleep is impossible until about 7 A.M. or later, when the desire for repose becomes urgent. The wakefulness during these hours is often incomplete; there is a state of drowsiness in which the spectres of all the disagreeable and horrible things which have ever occurred to the hapless wight are marshalled before him with ghoulish and gleeful insistence. When this kind of suffering has been in progress for some weeks, the patient shows signs of missing his proper amount of repose, the matter gets on his nerves, and he may even dread the approach of bedtime. It is a curious reflection that this drama, which if allowed to continue, may easily become a very serious tragedy, can be checked and cured by so simple an expedient as a few doses of common cooking soda. Fifteen to twenty grains of sodium bicarbonate in the form of

three or four tablets of soda mint, swallowed with half a tumblerful of hot water on retiring, will very often do all that is necessary in the way of neutralising the gastric hyperacidity; but it is well so to arrange matters that the dose can be repeated at about 4 A.M. if necessary. There are many elaborate preparations on the market for the relief of hyperchlorhydria, concerning some of which I can speak highly, notably bisodol and alkazane; but my present purpose is to emphasise the ease with which the condition can be cured by simple inexpensive every-day household means.

It would not be very difficult to draw a picture of the sort of rake's progress which a dyspeptic victim of insomnia is liable to make if the digestive cause of his trouble is not recognised in its early stages, but I forbear. I might, however, say that he would certainly start with veronal or some equally 'harmless' drug, and pass through 'rest cures' in nursing homes, suffer colonic assaults tempered by diathermy and high-frequency, drink waters at foreign spas, and compare symptoms at afternoon tea-tables, until he becomes a confirmed hypochondriac, who is a nuisance to himself and everyone else. And all for the lack of a little imagination, and a dose or two of sodium bicarbonate.

I should not like to leave the question of acid dyspepsia without a word as to two of its causes to which we are less often alive than we ought to be. One is eye-strain; the other, nasal obstruction. These by no means comprise the list, but most of the others are recognised and remembered, whereas these two very often escape. When a suitable alkali is only partially successful in relieving such symptoms as those above described, the refraction of the eye and the freedom of the nasal airway should be carefully tested, and if necessary corrected. Dyspepsia due to eye-strain is really very common.

Still more common, and unfortunately on the upgrade, is insomnia due to tobacco smoking. Whether the sleeplessness of smokers is due purely to dyspepsia, I dare not stop to inquire, though I may say that potent as smoking is in the causation of indigestion of a sly sthenic type, it is probable that the direct effect of the habit on the nervous system has a good deal to say to the insomnia from which sooner or later all smokers suffer. Nicotine, it would seem, differs from most other poisons in the fact it does not, by continued use, establish for itself a tolerance. On the contrary, the physiological tolerance with which we are all born wears itself out sooner or later, and when the limit is reached, symptoms of intolerance appear. I need not attempt to enumerate these; but heart-hurry and coarse tremors will occur to everyone as outstanding examples. Dyspepsia is a very common result of tobacco smoking, but being of gradual onset it is seldom attributed to its true cause. And with the dyspepsia comes insomnia, which, like dyspepsia, begins furtively, and is consequently saddled on to every cause but the right one. I have for many years charged my patients, and those who came to me for life assurance, to give up smoking before intolerance has had time to show itself; that is to say, to cease the stupid, and dangerous, and dirty habit on or before the forty-fifth birthday.

Admitting that the generalisation which ties insomnia to the cart wheels of dyspepsia is too inclusive, and selecting some other causes which may be placed in the same category, I find myself face to face with physical cold feet: a condition which is so generally recognised as to find a place even in many a textbook. The treatment, however, would seem to be so obvious as to require no mention in any of the classics. And yet it is well that the young practitioner should be able to tell his patients with emphasis that there is not the slightest objection to hot bottles so long as they are employed with intelligence. They should be used to warm the foot of the empty bed an hour or more before bedtime, and be removed to a portion of the bed remote from the feet, or altogether ejected, as soon as the bed is entered. This, because of the well-known, but hitherto unexplained, tendency of hot bottles to cause chilblains. Bed socks, too, are very efficacious, and

quite unobjectionable. Bed socks have cured more insomnia in brain workers than all the 'perfectly harmless' hypnotics in the trade circulars. There is another good way of warming the feet, namely, the ventral decubitus, to which I shall return presently. A hot bath immediately before retiring, if not too soon after a meal, is simple and effectual, especially for the occasional insomnia of worry and fatigue. General massage for half an hour before sleep time is very useful, but it has the demerit of being expensive. A fast is an excellent soporific. In one of his letters to Lord Chesterfield, Dr. Johnson signed himself 'Yours Impransus'. I feel sure the philosopher slept soundly that night.

The two ladies who kept house for Herbert Spencer, and related their experiences of the sage in a charming brochure, tell us that he insisted that his bed should be made over a dummy, so that the bed clothes should be comfortably loose to receive him. He had evidently had bitter experience of the obstinacy of chambermaids and nurses, especially trained nurses, who tuck in the bedclothes so tightly that they have to be levered out if anything like freedom is to be possible. The majority of people will tamely submit to these constricted discomforts, thinking that there is something esoterically hygienic about a bed which looks trim and neat. The vice of constriction, from which after all one can kick oneself free, is however as nothing to the vice of overloading with blankets and over-heating generally, which people do not seem to be able to recognise as a cause of insomnia, especially in children. I remember being hauled out one fine summer night to see a child of about three years, who was said to be seriously ill. I found him in a cot drawn up near a large fire; he was clad in flannel pyjamas, almost buried beneath blankets and an eiderdown, and surrounded by hot bottles. Escape from the toils of this foretaste of Hades was effectively prevented by a sort of fishing net well secured at head and foot. Needless to say he was perspiring freely, and was throwing himself about in a vain endeavour to get cool. Except for a slight cough, the most painstaking examination failed to reveal any abnormality whatsoever. So after giving instructions for the child to be given a tepid bath, and placed in a bed with one blanket, in a room with a window wide open, I went home. The next morning I received a message that the patient had had an excellent night and seemed perfectly well. Such in minor degrees, no doubt, but identical in principle, is the explanation of hundreds of cases of sleeplessness, especially in children. And by no means only in children, for over-loading with bed clothes is ridiculously common, almost as common as irrational clothing in the day time, which is admittedly rampant.

Not very long ago I was asked to see a man in a nursing home who could not sleep. My doctor friend assured me that the patient had been examined most carefully from every point of view, but no help towards a diagnosis had emerged. The fact that the patient obtained very little sleep was one to which the nurses would testify. Also there was no doubt that he was losing flesh. When I came to examine him I found it quite difficult to undo the neck button of his pyjamas, and ventured to suggest that this constriction of his neck could account for his want of sleep. The suggestion was not well received, but in the long run it turned out to be correct. In seeking for a cause of insomnia it is imperative that all constriction, however slight, and however seemingly unimportant, should be discovered and removed. I have known the unbuckling of sock suspenders on a railway journey to give sleep to a weary man who was so accustomed to them that he did not realise that he was wearing any.

If you will go into a children's ward when the children are all asleep, you will find the majority of them lying on their faces. When I first observed this and pondered over the cause, I was inclined to attribute it to an instinctive attempt to relieve the heart and great vessels of the weight of the thymus gland, which in childhood is much more considerable than one is inclined

to think. I am still of opinion that such is one of the factors, but I now realise that there are others. One is the drainage of the frontal sinuses; another the relief of the circulation in the pulmonary bases; but the most important is the re-location of the abdominal viscera in their normal quadruped position. Adults are very partially adapted to the upright posture, but children are scarcely at all so adapted; they therefore re-become quadrupeds whenever they get the chance, and nature finds in the long hours of sleep a splendid opportunity of redressing the balance. Why it is that the ventral decubitus should promote warm feet it is difficult to say, but there can be no manner of doubt as to the fact. I have often adopted this position in order to get my feet warm, and have never been disappointed in the result. It may be that the trunks of the large abdominal vessels, being thus relieved of the weight of the ponderous viscera, the circulation of the feet is facilitated. At any rate, whatever the details, it is obvious that the mechanism of the circulation generally is simplified by the ventral decubitus, with great advantage to its efficiency.

Another simple means of assisting the circulation during the night season and thus promoting sleep, is to ensure that the bed shall be at least four inches higher at feet than at head. This brings gravity to the aid of the venous return, with consequent lessening in the force demanded of the systole. Ordinary fracture blocks are all that is necessary, and where these are not obtainable, a little imagination will furnish substitutes. And let it not be forgotten that this inclined plane of the trunk means that the work of the all-important ascending colon is now downhill instead of uphill, an advantage which needs no emphasis.

Drops in the Eyes

(From the *American Journal of Ophthalmology*,
October 1932, Vol. XV, p. 969)

Of the men who lie awake trying to decide whether to operate for a detached retina, or about adopting a certain technic for cataract operations, how many give a thought to the method of putting drops in the eyes of a patient? Yet the latter will be important to one thousand patients for every one who will need either of the operations mentioned; and the drops may affect the success of any operation. The doctor who thinks little about the matter naturally leaves 'drops in the eyes' to the uninstructed nurse or mother. He takes the attitude toward drops, of Dogberry in Shakespeare's play, who says: 'To write and read come by nature'. If it comes by nature, who can expect the doctor to waste his time to teach a mother, or nurse, how to put drops in the eye?

The first drop of the local anæsthetic may decide the success, or failure, of the operation. The dropper, held too far above the eye, the cocaine solution a little too warm, or too cold, the drop strikes the eye with a distinct shock. The patient tense, and the eye full of tears with the excitement, the eye squeezes shut, the bulk of solution goes out of the eye, and there is no anaesthesia. The surgeon, conscious of other operations he must do in the hour, proceeds to inject novocain in spite of the complaints and contortions of the patient; and co-operation necessary for the operation becomes impossible for that patient. Before it is over the surgeon may be in a condition that makes a good operation impossible.

Drops to produce cycloplegia, mydriasis, or miosis must penetrate the cornea and enter the aqueous humor. A grain of atropin absorbed through the conjunctiva has less effect on the pupil, or ciliary body, than if it had been injected into the arm.

To produce cycloplegia, a sufficiently concentrated solution of atropin must remain in contact with the cornea, long enough for the drug to be absorbed into the corneal tissue, whence it will diffuse into the aqueous humor. No amount of it, poured into the conjunctiva to be absorbed into conjunctival vessels and the general

circulation, or run through the lacrimal passages, drying the throat, or causing atropin poisoning, will have the desired effect on the iris, or ciliary muscle. In similar fashion a nurse, putting eserin drops in the eye of a glaucoma patient, may be effectively contracting the pupil, or causing agony from ciliary spasm, according to the knowledge of the effects of eserin that has 'come by nature' to the doctor who prescribed it. If practised like the ritual, which proved effective in bringing 'votive offerings' in Greek temples, before the days of Hippocrates, it may be as useful when practised by a nurse in white uniform, as by a doctor, who has a diploma from a Class A medical school.

To the doctor who is trying to make scientific observations, each drop instilled in the eye is an opportunity to learn something about that eye and the patient; and perhaps something that he has not observed about any eye, or patient before. Observations can be significant, even when one does not have a knife in one hand and forceps in the other. The frequency and importance, even of idiosyncrasy, is worth knowing.

A drop of homatropin solution, placed on the upper limbus, spreads rapidly over the whole cornea and can be watched until it is evenly diffused over the surface. If there is a spasmodic attempt to close the lids, it may be due to shock of the drops falling more than an inch or two, or from the solution being too warm or too cold, or to the neurotic condition of the patient. An acid solution of the drug, or a drop from the wrong bottle, containing an irritating solution, will provoke closure and squeezing of the lids a little later. At least the physician who instils such drops and watches the effects, gets an idea of the efficiency of each application; and can judge better as to the significance of unusual symptoms that may appear, or the number of instillations and time that will be required to secure the maximum effect. It is not a waste of time to become better acquainted with the patient, even if one does not intend to extract a cataract, or make a diagnosis of brain tumour.

Drops are put into the eye for other purposes than to cause cycloplegia; and for each different purpose differences of technic are needed to make the application most effective. If this duty is left to the nurse, or mother, that person should be instructed how to do it. A doctor sent a girl home stating that he wanted the pupils dilated with one per cent. solution of atropin. She returned with the pupils of normal size; and reacting perfectly to light and accommodation; except that one pupil was a trace larger than the other. The bottle of drops was brought along. A drop from this bottle was placed on the upper edge of the cornea, and the upper lid held against the brow for a half minute. In ten minutes the pupil was widely dilated and fixed. In one hour the accommodation was fully paralysed. The grandfather, who brought the child, watched the proceeding with evident interest. Then he said: 'Yes, I put the drops in every time, three times a day. But I did not do it like you did'.—Edward Jackson.

Lead in Urine

By T. C. BOYD, F.I.C.
LIEUTENANT-COLONEL, I.M.S.

and

H. D. GANGULY, M.Sc.

(Abstracted from the *Indian Journal of Medical Research*, Vol. XX, July, 1932, p. 75)

ANALYTICAL METHODS FOR THE DETECTION OF LEAD
Broadly speaking these may be classified into:—

- (1) Chemical methods.
- (2) Micro-chemical methods.
- (3) Spectrographic methods.

A perusal of the current literature will impress the enquirer with the many methods that can be applied to this problem under the heads (1) and (2). In this paper, however, we propose to restrict ourselves purely to the micro-chemical tests and particularly to the

triple nitrite test of Behrens and Kley, in which the presence of lead is proved by the formation of the crystalline compound $K_2Cu Pb(NO_2)_6$ readily recognized under the microscope. Lawrence T. Fairhall of the Harvard Medical School has given an excellent account of his method (Journal of Biological Chemistry, 1923) and we have followed closely his technique in the actual application of the test itself.

GENERAL PROCEDURE ADAPTED

(1) *Collection of the urine.*—This was collected direct where possible into Pyrex flasks which before despatch to the wards were prepared by treating them with 100 c.c. of lead-free hydrochloric acid specific gravity 1.124 and heating on the waterbath for three hours, then subsequent treatment with dilute nitric acid for one hour and finally washing with double distilled water and draining. Officers sending in specimens to the laboratory appear to neglect the importance of clean lead-free containers and possible contaminations from urinals, etc. The urine should also be freshly collected as we find that when fresh it ashes more easily. We need not refer again to the importance of the preparation of the glassware used in the test, nor to the necessity of being certain that all reagents are lead-free.

(2) *Ashing of the urine.*—One litre of the urine is evaporated to dryness in a porcelain basin on the waterbath and the residue completely ashed in a silica or porcelain crucible the former is preferable. The time required to ash the residue obtained from one litre takes about twenty-five hours over the Bunsen flame.

(3) *Fairhall's application of the Behrens Kley triple nitrite test.*—The ash obtained is moistened with distilled water, twenty-five c.c. and fifteen c.c. of pure hydrochloric acid specific gravity 1.124 added, this treatment does not cause complete solution of the ash, a little white gelatinous matter is left undissolved. A few drops of methyl orange are now added as an indicator and excess of acid neutralized with ammonium hydroxide to a final pH of approximately 3.8. Particular care must be taken to adjust the reaction or the lead will not be completely precipitated. The whole is now transferred to a centrifuge tube and freed by spinning from the undissolved precipitate. (We have found that examination of the gelatinous precipitate usually reveals the presence of lead where the final result of the test is positive.) Two c.c. of a saturated solution of ammonium sulphate and a drop of a two per cent. copper acetate solution are now added and the whole saturated with sulphuretted hydrogen for at least half an hour. The precipitated sulphides are separated by the centrifuge and thoroughly washed three times with double distilled water, the final wash water is removed by means of a capillary pipette. The tube containing the precipitate is now placed in a beaker of boiling water and two drops of nitric acid specific gravity 1.140 added followed by two drops of water. When solution is complete the whole is removed and evaporated to dryness on a microscopic slide, when dry 0.005 c.c. of a four per cent. sodium acetate solution is added and evaporation to dryness again carried out. The slide is now allowed to cool at room temperature, when cool the residue is treated with 0.005 c.c. of acetic acid and a small crystal of potassium nitrite. Five minutes are allowed to elapse when the slide is examined under the microscope for the characteristic crystals. The examination should not be delayed too long as we find that in this hot damp climate the crystals are liable to disappear. One other point that requires attention is that when dissolving the precipitated sulphides with nitric acid, the tube should not be left in the boiling water longer than one minute as some of the sulphur is oxidized to sulphuric acid which interferes with the test.

Sensitivity of the test.—Experimenting with known dilutions of lead in water, we found this test to be sensitive to 0.00003 mg., the figure given by Behrens and Kley.

SUMMARY OF RESULTS OBTAINED

Of the twelve cases examined under the European series lead was detected in ten.

Of the twenty-four cases examined under the Indian series lead was detected in two only.

Of the seven suspected Indian lead poisoning cases lead was detected in four.

The difference found between Series I European and Series II Indian is worthy of note.

It is of interest to compare these results with others obtained by workers outside India.

Francis, Harvey and Buchan, *Analyst*, December 1929, p. 725, found that in fifty-five samples of urine examined by them lead varied from nil to 0.133 mg. per litre giving an average of 0.040 mg.

Cooksey and Walton (Office of the Director-General of Public Health, Sydney), *Analyst*, February 1929, p. 97, found in normal urines a lead content of from 0.02 mg. to 0.05 mg. per litre.

Fretwurst and Hertz, *Archiv. Hyg.*, 1930, found in normal urines lead varying from 0.01 to 0.07 mg. per litre and in workers exposed to lead but showing no toxic symptoms 0.02 to 0.9 mg. per litre. Kehoe and others, *Jour. Amer. Med. Assoc.*, 1926, p. 2081, found that normal workmen pass lead in the urine and faeces, and further that there is no diagnostic value in qualitative lead determinations in the excreta of persons suspected of having lead poisoning and at present no quantitative expression of lead excretion in man which may be said to be significant of impending or present lead poisoning.

Edwin Bramwell in an article in the *B. M. J.*, 1931, July 18th, mentions two hundred cases of suspected lead poisoning in the Mayo clinic where one hundred were excreting lead and points out that the presence or absence of lead in the urine is a point to which too much importance must not be attached.

Millet, *Jour. Biol. Chem.*, 1929, LXXXIII, p. 265, points out that the major part of the lead injected in cancer cases is excreted in the faeces and that there is no evidence that the lead injected is excreted in the urine.

In an article by I. A. Christiansen, G. Hevesy and S. Lomholt abstracted in the *Analyst*, 1924, October, p. 490, it would appear that the greater part of the lead accumulates in the liver from where it is slowly excreted in the faeces, and also that considerable amounts are found in the intestines and kidneys.

DISCUSSION

Objections may be raised to the method of analysis employed on the grounds that there may be an appreciable loss of lead in the ashing, loss may also occur in the precipitation process, in addition, from the practical standpoint, it may be urged that the time required for the analysis is too long and that the collection of a litre of urine under supervision especially in a hot climate is difficult. Further the method is not quantitative. We are fully alive to all these criticisms but the object of our investigation was to find out if the excretion of lead was common in this country and, if so, was it equally distributed amongst the different classes of the community. Our results show that amongst Europeans it is extremely common but that where Indians are concerned the amount of lead excreted in the urine falls outside the limit of sensitivity of the method employed. Why there should be this difference we are unable at the moment to explain and can only record our findings.

CONCLUSIONS

We have recorded the result of examinations made on urine for the determination of lead on various classes of the community and as far as Europeans are concerned this appears to be commonly present while in the Indian groups of the community the excretion of this element appears to lie outside the sensitivity of the method employed.

Finally, we have drawn attention to the fact that the views of certain investigators appear to indicate very strongly that the detection of lead in urine, or even its quantitative estimation, is of very doubtful value as far as the diagnosis of lead poisoning is concerned.

Reviews

A MANUAL OF BACTERIOLOGY MEDICAL AND APPLIED.—By Professor R. T. Hewlett, M.D., F.R.C.P., D.P.H., and Professor James McIntosh, M.D., B.Ch. Ninth Edition. London: J. & A. Churchill, 1932. Pp. ix plus 746, with 43 plates and 66 figures in the text. Price, 18s. net.

The ninth edition of Professor Hewlett's well-known textbook of bacteriology has now appeared; this edition was produced with the collaboration of Professor McIntosh whose name appears on the title page for the first time. Although the eighth edition was published only six years ago, it is surprising to note the number of alterations and additions that have been made in this last edition. It has been thoroughly revised and brought up to date, both by the introduction of new matter and by the omission of old matter and less important passages.

Such subjects as the handling of the microscope, the preparation and standardization of media, serological tests, and the bacteriological examination of water, air and soil are fully dealt with. The systematic study of bacteria is all that could be desired and the student will find in this book simple, straightforward and clear accounts of most of the recent work. The section on ultra-microscopic organisms has been extended and a fuller account of virus diseases has been given. Bacteriophage, however, is considered very briefly, only four and a half pages are devoted to this very important subject, and there is nothing to help the student in the study of bacteriophage. The spirochaetes and spirochaetosis, with syphilis, have been separated from the

protozoa, and constitute a new chapter, and a full account of the Kahn test is included. We would have wished for the total exclusion of the chapter on protozoa from a textbook on bacteriology. For the student in the East a chapter of only forty pages devoted to animal parasites such as the pathogenic amœbæ, trypanosomes, leishmania, coccidia and plasmodia cannot be of much value. A chapter dealing with the physiology of bacteria would have been very valuable to the student of bacteriology. This is a branch of the subject which, though of fundamental importance to the proper study of bacteria, has been persistently neglected or insufficiently dealt with in the textbooks of bacteriology.

On p. 388 it is stated that in the East the Shiga strain of dysentery is the predominant infection, and in the West the Flexner strain. This is not in accordance with the findings in India where the majority of the cases of bacillary dysentery are due to the Flexner strains. The only other criticism that we have to offer is that the tables on pages 400 to 405, showing cultural reactions of certain aerobic non-spore-producing intestinal bacilli with the names of bacteria in alphabetical order, would have been better had the bacteria been grouped according to their cultural reactions.

Several excellent new plates and new figures have been added in this edition and have enhanced the value of this book. Altogether this is an excellent textbook and one that may be very cordially recommended to the student of bacteriology.

welfare of the people. In addition there are purely voluntary agencies working on self-supporting lines while others, though independent in control, receive official assistance and grants. The author is insistent that *every* agency should co-operate and that there should be all round co-ordination of work.

Being itself a very condensed compilation from various sources, it is difficult to review the book without practically quoting the whole of it. Mr. Brayne's work in Gurgaon is well known and has been a great stimulus to work in other places, though the work was expensive and has practically died since its promoter left the district. Still it showed what could be done with the villagers of India. The shrewd statement is made that health, agriculture, and veterinary service only appeal to the villager if his life is worth while to him and it is the educationists' task to make him understand how worth while his life might be. We get here to the great difficulty of defining what constitutes human happiness. One point which is brought home is that education in India has a remote and abstract quality about it which more than often defeats its object. Education should have an intimate connection with home life—secondary education in India has very little of this, and the young are not taught to plan their lives in relation to their

own conditions and their own future. The object of rural reconstruction is to educate, but to educate in all directions; the horizon must be pushed back in all directions at once. The various methods of attempts at rural construction are outlined. In the south, welfare centres are used, usually under the auspices of the Y. M. C. A.; in the Punjab and the United Provinces there are official rural community boards, of which a minister is chairman; in Bombay the taluka development associations unite official efforts with the leading citizens of the neighbourhood; the eastern provinces of Bengal, Assam, and Bihar and Orissa are without any definite official department, so-called, for co-ordinating Government and private agencies, though there are a good few of the latter, such as the co-operative anti-malarial societies and women's institutes like the Saroj Nalini Dutt Association. Dr. Rabindra Nath Tagore's rural university stands in a class apart, though it remains to be seen whether it will survive apart from Dr. Tagore's stimulation and inspiration.

The lines of the pamphlet are indicated and it is an important contribution to a subject which every worker here has at heart, namely, the improvement of the lot of the Indian peasant.

A. D. S.

Annual Reports

ANNUAL REPORT ON THE RANCHI INDIAN MENTAL HOSPITAL, KANKE, FOR THE YEAR 1930. PATNA, 1932, SUPDT., GOVT. PRINTING, BIHAR AND ORISSA. PRICE, RE. 1-4.

The following are abstracts from this very interesting report by Major J. E. Dhunjibhoy, I.M.S., the Superintendent of the hospital:—

The accommodation of the hospital remained the same as in the previous years, viz, 1,014 for males and 272 for females, total 1,286, which is apportioned in the proportion of three-fourths, and a quarter to Bengal and Bihar and Orissa respectively.

The male section of the hospital remained overcrowded throughout the year under report but to a lesser degree than in the previous years. The restriction which was imposed by Government on the admission of harmless and non-dangerous male patients in the previous years was also in vogue during the year under review, and only carefully-selected cases who were certified as dangerous and unmanageable at home or elsewhere were admitted, for this 50 extra emergency beds were sanctioned by Government. The overcrowding of the hospital, its causes and the steps proposed to be taken have been fully dealt with in the last Triennial Report (1927—29) of this hospital. Owing to financial stringency none of the additional buildings, included in the scheme of expansion of this hospital which has been accepted by Government, could be taken up during the year under report.

Patients.—The following table shows the number of patients resident in the hospital on the 1st January of 1930 and of the previous two years:—

Years	Male	Female	Total
1930 ..	1,049	215	1,264
1929 ..	1,065	209	1,274
1928 ..	1,160	234	1,394

It will be evident from the above figures that the congestion in the male section has been gradually relieved. On the 31st December, 1930, there were only 1,034 male patients resident in the hospital, i.e., the male section was overcrowded by only 20 patients at the end of the year under report.

In this large hospital there is a large number of chronic, incurable, harmless and homeless patients who were originally transferred from the old hospitals of Berhampore, Dacca and Patna. These chronic and incurable patients unnecessarily occupy the beds and

thus prevent the admission of those patients who really require the immediate attention and treatment of this institution.

I have, therefore, proposed to Government to open a 'chronic' depôt for these harmless and homeless patients, as they can derive no further benefit by their stay in this modern hospital. Such a depôt can preferably be opened in one of the old abolished mental hospitals either in Bengal or Bihar and Orissa.

Special efforts were made during the year under report as in the previous years to discharge 13 chronic and harmless patients to the care of their relatives who could be traced by the magistrates of their districts, as a result of which 10 patients were handed over, and the plea of inability which was put forward by the relatives of 3 patients to take them over was accepted by the committing magistrates and they were, therefore, not discharged.

The following table shows the ratio per cent. of cases cured to the total admissions during the year under report as well as in three previous years:—

Years	Male	Female	Total
1930 ..	23.49	22.22	24.24
1929 ..	16.94	22.22	18.60
1928 ..	30.86	16.00	27.36
1927 ..	30.87	13.20	27.41

Death rate.—The percentage of deaths to daily average strength during the year under report and in the two previous years is shown in the following table:—

Years	Male	Female	Total
1930 ..	2.02	2.29	2.07
1929 ..	1.91	2.39	1.99
1928 ..	3.41	3.66	3.45

The general health of the patients was good throughout the period under report. The daily average number of sick treated in the infirmaries for bodily ailments was 59.93 males, 1.67 females and 61.60 total against 53.95 males, 3.47 females, total 57.42 in the previous year.

Statement VI shows the types of insanity of the patients admitted during the year under report. Mania, melancholia, dementia præcox, toxic insanity and confusional insanity were the principal types treated.

Paying patients.—Seventy-nine patients (60 males and 19 females) were treated during the year under

report as compared with 60 (48 males and 12 females) in 1929. During the year under report as well as in the last two years several applications for the admission of paying patients had to be refused for want of accommodation in the male section.

The scheme for the construction of paying patients' wards has been deferred by Government owing to the financial stringency. In the meantime, the arrangement of keeping the paying patients of the male section in a separate ward of one of the quiet patients' blocks is continuing. A few suitable patients are also given single rooms from time to time when available. In the female section, although there is no separate paying patients' ward, first class paying patients are given separate rooms and other classes of patients are kept in separate wards in the infirmary block. This comfort for female paying patients is possible at present, as there is no overcrowding in the female section.

Suicide.—I am glad to be able to report that there was no case of suicide during the year under report and the previous three years in spite of the fact that there are more than 70 suicidal patients in the hospital, the majority of whom are potential suicides. Several serious attempts were made by potential suicides to end their lives generally by trying to strangle or hang themselves.

It is satisfactory to note that there was no case of serious accident or injury during the year under report in spite of the fact that all patients admitted during the year were sent here as definitely dangerous. There were a few minor accidents and injuries but none were serious. This result can fairly be attributed to the kind treatment meted out to this class of patient in this hospital as already stated in my annual report of 1928.

Treatment of mental conditions.—*Hydrotherapy (prolonged bath).*—During the year under report 69 cases were given this treatment as against 43 in the previous year. The average number of hours of immersion per patient was 146. The result of the treatment was most encouraging. A special hydrotherapy ward has not yet been provided for want of which this important form of therapy could not be more extensively used.

Dietetic.—Special attention is paid to the proper dieting of patients of this hospital as a well-balanced nourishing diet largely helps the recovery rate. The weight charts of the patients showed a general rise throughout the year under report. The average gain in weight per patient during the year under report was 2.00 lbs. per every male patient and 0.85 lb. per every female patient.

Artificial feeding.—Cases refusing food were spoon-fed by nurses and attendants, recourse to artificial feeding being resorted to in the few special cases exhibiting active refusal to food.

We have many stuporous cases of various degree which often require artificial feeding by tube either per nose, mouth or rectum, and I should like to mention one case of benign stupor that was kept alive for 3½ years by nasal feeding twice daily.

Occupational therapy.—This therapy is the sheet-anchor of our treatment in this hospital, and has been carried out as vigorously as before. Patients of both sexes are suitably employed chiefly in gardening, weaving, cane and bamboo work, smithy, carpentry, tailoring, cobbling, mending clothes, mattress and pillow-making, lace-making, knitting, embroidery work, domestic and office work, etc., etc. The patients' labour is fully utilized towards supplying the needs of the hospital. Jharans, dusooti cloth, bandage cloth, asans and many other useful articles required for the hospital are manufactured in the occupational therapy classes. The weaving section in the female section was considerably expanded during the year under report but the progress was hampered for want of a weaving instructress, this post was sanctioned by Government but no appointment was made for want of funds. The vegetable garden of this hospital is entirely run by the patients' labour and the hospital is entirely self-supporting as regards its vegetable and fruit supply.

The average daily number of patients employed in the vegetable garden was 139 in 1930, 145 in 1929 and 142 in 1928.

The construction of four wells in the garden area for the purpose of irrigation was taken in hand during the year under review, by the Public Works Department and the work is expected to be completed in 1931-32.

Drugs.—(a) On my return from leave I introduced what I had seen in Zurich Hospital, popularly known as Zurich treatment. It consists of heroic doses of sodium luminal gr. xii per day given by mouth or by deep intramuscular injections in the buttock. It is continued for over a fortnight. It is very beneficial in cases of acute excitement with intractable insomnia. We tried it in several of our cases of this type and the results were very encouraging but unfortunately the benefit was temporary.

(b) Deep intramuscular injections of paraldehyde. Paraldehyde was also injected daily in the buttocks for a period of a fortnight in highly excited cases. The results were very encouraging but the benefit was temporary.

(c) During the year under review bromo-chloral co. was also prescribed by me to some mild as well as intractable cases of insomnia. In some cases the drug acted like a charm but failed in others.

In fact all the above drugs tried in the way described above during the year under report have come to stay on our register of drugs for insomnia and general excitement.

Organotherapy.—Nineteen patients were treated with different glandular compounds during the period under review but the results were not very encouraging. Thyroid was found to be a very good activating agent when given in large doses for a period of 10 days in acute melancholia and mild stupor cases.

Physiotherapy.—Strictest attention is paid in this hospital to correct all physical defects before an attempt is made to explore the psychological defects. Tonsils, nasal sinuses, adenoids, eyes, ears, etc., are contributory causes to mental derangement when they are defective. Therefore on admission of a patient all physical avenues which are believed to contribute a smaller or larger share in the causation of mental diseases are thoroughly explored.

Teeth.—(a) The services of a whole-time dentist on the staff are desirable but funds have not been forthcoming.

Throughout the year under review and the previous years, Dr. D. R. Choudhury, one of the sub-assistant surgeons on our staff, treated the teeth of a number of the patients.

(b) Similarly, Dr. P. C. Das, M.B., who is happily also an eye specialist, did excellent work with the ophthalmoscope and operated on some cases of cataract among the patients.

(c) **Syphilis.**—During the year under report, 425 blood specimens were sent to the Pathological Laboratory of the Prince of Wales Medical College, Patna, for the Wassermann test and suitable anti-syphilitic treatment was given to positive cases.

(d) **Leprosy.**—During the year under review we were obliged to treat three highly-contagious positive cases of leprosy in the hospital as those cases were not admitted in the Albert Victor Leper Hospital, Gobra (Calcutta), for want of accommodation. This is admittedly a serious state of affairs, which would be remedied if the Government of Bengal could arrange to reserve a few beds for this hospital in the Albert Victor Leper Hospital at Gobra for the treatment of such acute cases. To treat highly-contagious leper cases in a mental hospital is undesirable for obvious reasons.

Malarial therapy.—During the year under review four patients were given malarial therapy with indifferent results.

Sulfosin therapy.—On my return from leave during the latter part of the year under report I have injected a few selected cases with sulfosin (which is 1 per cent. solution or suspension of sulphur in olive oil). Dr. Knud Schroedor, an eminent physician of

Denmark, in 1929, claimed to produce pyrexia by injections of sulphur in olive oil better than that produced by malarial therapy. So far we agree with his claims as our patients have shown a steady rise of temperature up to 103 degrees after every injection. The results of our experiments will be fully given in our next annual report as at the time of writing this report the treatment is still under trial and not yet completed.

Psychotherapy.—A case was admitted from Calcutta as one of complete paralysis of both legs with mental excitement. The patient was brought into the hospital on a stretcher. On examination the case was diagnosed as one of 'conversion hysteria' and the patient, who was treated as a case of paralysis of the legs for three months outside, was made to walk within eight days of his admission and was discharged cured within two months, and he went to Goa—his native place—which is a distance of 1,500 miles from Ranchi.

We rarely see such early cases admitted into this hospital. We are only called upon to treat all chronic cases whose relations and friends have kept them in their homes for years under treatment of every one but a psychiatrist, and who are only sent to us when they become unmanageable and dangerous at home. This is further aggravated by the present unavoidable congestion of the hospital with the result that cases are allowed to remain untreated in jails or houses until such time as accommodation is available. In spite of all these difficulties I am happy to be able to report that our proportion of cures to so-called new admissions as well as to average strength of the total population, can proudly be looked upon as extremely good.

Sports and amusements.—Both indoor and outdoor games were played by quite a large number of patients and they all seemed to take more active interest in the matter. Several football and hockey matches were played by the hospital team, consisting of staff and patients, against several other units at Kanke and Ranchi. Several patients of both sexes played tennis and badminton.

Musical and other entertainments.—In the absence of a proper amusement hall, which is a pressing need of the hospital, one of the dormitories of a quiet patients' block, is utilized for the purpose. Twelve theatrical performances both Hindi and Bengali and several musical soirees got up by the staff and patients were staged during the year under report, to the great enjoyment of patients of both sexes. A few well-known magicians entertained the patients. Besides, the patients of both the sections were entertained by the musical entertainer on every alternate day. Gramophones are played by the patients every evening in different wards by turn. The radio set, which was installed in 1929 out of a special donation made for the purpose by Raja B. D. Birla, was a source of great amusement to patients. The concert party of the hospital which was only organised a couple of years ago played both Indian and English music throughout the year and afforded another source of great pleasure to patients. Its existence and the maintenance of the high standard of music are entirely due to the enthusiasm and perseverance of Sub-Assistant Surgeon Dr. Dhaniraj Choudhury. The band also played at patients' games and theatricals. A few musical instruments were purchased during the year.

Picnics.—During the fine weather large numbers of patients picnicked out on the nearest hills, riversides, gardens, etc., with the hospital concert party. Those outings were very much enjoyed by them.

Parole.—Many dependable patients were granted full 'local' and 'Ranchi' paroles. Others were allowed out both morning and evening for walks with attendants. None of the patients granted parole abused the privilege, and the number of patients on parole is increasing every year. The effect on the health of patients has been striking.

Drives.—Patients of both sexes were sent out regularly by turn throughout the year for motor drives both morning and evening in the hospital cars.

Expenditure.—The total expenditure exclusive of the amount received from the paying patients and miscellaneous receipts was Rs. 5,70,175-4-7 during the year under report as compared with Rs. 7,60,978-7-1 in 1929 and Rs. 6,34,085-1-6 in 1928.

Annual average cost per patient.—The following table shows the annual average cost per head during the year under report and the two previous years:—

Years	Annual cost per head inclusive of Public Works Department charges			Annual cost per head exclusive of Public Works Department charges		
			Rs. As. P.			Rs. As. P.
1930			453 3 0			390 5 9
1929			605 5 3			418 7 4
1928			475 14 3			357 3 2

During the year under report medical students from the Prince of Wales Medical College, Patna, were sent in two batches as in the previous years, for intensive training in mental diseases as required by the curriculum of the Patna University for the degree of M.B., B.S.

The medical and nursing staff of this hospital were also allowed to attend these lectures and demonstrations.

REPORT OF THE DIRECTOR OF PUBLIC HEALTH OF MADRAS PRESIDENCY, FOR 1931. BY LIEUT.-COL. J. R. D. WEBB, O.B.E., I.M.S. MADRAS: SUPERINTENDENT, GOVERNMENT PRESS, 1932. PRICE, RE. 1-2.

Economic distress, diminished incomes and revenues, and the stern necessity for retrenchment in staff, salaries and activities are familiar notes in every annual report for 1931. The present report is no exception. Two first class Health Officers have been retrenched and the Professorship of Hygiene held in abeyance. This is Colonel Webb's first annual report and an air of optimism pervades it which augurs well for the progress of the public health of the Presidency under his guidance.

The population of Madras province in 1931 was determined by Census as 46,740,107, an increase of 4,421,122 over that of 1921 representing an increase of 9.46 per cent. This is the highest rate of increase for the last three decades. Colonel Webb gives some interesting paragraphs on the calculations of birth and death rates in intercensal years, showing the fallacies of determining them on censal populations. The whole of Indian statistics are vitiated in this way and towards the end of intercensal periods, both birth and death rates are much higher than actuals; then in the census years there is a sudden drop in these rates due to the new increased census number being taken as the denominator. We believe the point is being taken up by the Public Health Commissioner with the Government of India. On the new population, the birth and death rates of the province were 35.54 and 23.72 per 1,000. Registration is still deficient all over but there are very definite signs of improvement. As regards disease the year 1931 was a severe epidemic of cholera all over the province. There is a tendency for such a recrudescence every 5 or 6 years and from statistical study an actual increase had been forecasted and certain measures of prevention and protection put in train before the actual increase occurred. As is usual in Madras, the epidemic was most severe during the months of the north-east monsoon, i.e., in the first quarter of the year. Cholera bacteriophage was prepared on a small scale by the Director of the King Institute and given in 17 cases as a remedial measure. It was not tried as a prophylactic. Rs. 3,000 was devoted to an experiment as to the value of bilt vaccine but the results have not yet been analysed.

Improvement of elementary sanitation, i.e., the provision of a pure water supply and the sanitary disposal of night-soil, proceeds but slowly, but in some districts definitely. In one district for instance over 2,000 bored-hole latrines were established.

Malaria is a severe disease in Madras taken as a whole. Retrenchment necessities did away with the temporary malarial establishment. Such anti-mosquito measures as were carried out gave good results. There are some interesting paragraphs on beri-beri and epidemic dropsy. The report does not give the distinguishing points between the two diseases. Colonel Webb adduces evidence that beri-beri is an infection picked up from the soil, and that epidemic dropsy is not due to rice but to mustard oil adulterated with odismari (*Americana mexicana*). A more critical and detailed report on these statements is desirable. The evidence is merely stated and the opinion of the Director of Public Health may be quoted as authoritative.

Glove-oiled vaccine lymph is now being issued from the King Institute and has been found to be very successful. Further trials are being made and reports of these will be awaited with interest. Vaccination (primary) is compulsory in most areas, but responsibility for prosecutions is in many cases being evaded by chairmen of district boards. Fear of unpopularity explains these deviations from responsible duty. Control over district vaccinations is also divided and this does not help matters.

Maternal and child-welfare work is being carefully fostered, and there is an all-time Assistant Director of Public Health for maternity and child-welfare work. Infantile mortality rates are still high (186.6 per 1,000 births). The work undertaken however has necessarily been rather of an elementary character, i.e., the feeding and bathing of children. The principles of proper welfare work are quite thoroughly understood but there are difficulties in the way. Despite the Madras Nurses and Midwives Act of 1926 which requires registration of all trained midwives, there are still hundreds of untrained barber midwives. Maternity and child welfare work is not included in the work obligatory under the Local Boards and District Municipalities Acts. The report also contains that of the Sanitary Engineer to the Public Health Department. This department had dealt mainly with water supplies, of which five new installations were completed during the year.

THE MISSION TO LEPERS. REPORT OF FIFTY-EIGHTH YEAR. AUGUST 1932.

A REVIEW OF THE YEAR'S MEDICAL WORK

The Mission to Lepers is a progressive body—of that, perusal of the last few annual reports leaves little doubt. The 'Asylum', a resort for those without hope of recovery, has given place to the 'Home' and 'Hospital' within the last few years. Some twelve years ago treatment consisted of palliatives alone; the following statistics for the past year tell a very different tale:

Mission to Lepers for India—Statistics of Treatment

Inmates who received treatment for three months and upwards	5,524
Much improved	1,877
Slightly improved	2,023
Inmates who became worse	399
Had to stop treatment or left	759
Cases arrested <i>without</i> deformity	450
Cases discharged <i>without</i> deformity	311
Cases arrested <i>with</i> deformity	337
Cases discharged <i>with</i> deformity	81
Cases arrested <i>without</i> deformity in a previous year, but relapsed during the year	31
Number of out-patients treated	4,418
Cases arrested or became symptom-free (from among out-patients)	29

In many of the institutions the majority of the patients now come with the distinct object and hope

of getting better, and for many of them that hope has not proved a vain one.

Though many of the homes are constantly being enlarged, their accommodation cannot cope with the demand for admission, and one of the saddest duties of the superintendent is often to turn away those who have travelled long days of painful and wearisome journeying, for lack of room.

What strikes one when one visits such Homes as Purulia, Raniganj, Chandkuri and many others, is the look of hope and cheerfulness on the faces around one; the cheerfulness of having daily work to do and being able to do it. The sympathetic organization of labour according to ability to do it is one of the most important parts of the treatment. Leprosy can be treated successfully only by the expert, but the doctor must also be an expert in the treatment of all the scores of ailments which complicate and amplify leprosy if he is to make any headway. Such doctors are not lacking on the staff of the Mission to Lepers in India, and their number and usefulness increases year by year.

But seventy-five per cent. of the treatment lies in the hands of the patient himself, and without his full co-operation there is little hope. It is only by sympathetic and understanding training, often through long months and years, that the patient can be taught to do his part; and this is where the idealism and personality of the mission superintendent, doctor and nurse are most severely tested.

The out-patient clinic in connection with the leper home is a new feature of recent years. Last year four out of every nine cases treated were out-patients, and the numbers would be far larger were the staff available.

Correspondence

PANTOCAIN—A NEW COCAINE SUBSTITUTE

To the Editor, THE INDICAL MEDICAL GAZETTE

SIR,—Messrs. Havero Trading Co., Ltd., were good enough to supply me a one gramme bottle of their new product, Pantocain, for clinical trial.

Pantocain is p-butyl-amino-benzoyl-amino-ethanol-hydrochloride. The makers recommend this drug for anaesthesia of practically every region of the body.

I used the drug on a series of over fifty consecutive operations on the globe of the eye, most of them for cataract, some for acute and chronic glaucoma. The strengths of the various solutions employed were as follows: viz, a 1 in 200 solution for superficial anaesthesia by instillation into the conjunctival sac, a 1 in 500 solution for akinesia of the orbicularis oculi by blocking the seventh cranial nerve, and a 1 in 250 solution for anaesthesia of the iris by blocking the ciliary nerves. A few enucleations also were performed under local anaesthesia with this drug. The anaesthesia and akinesia were perfect in every way in all the cases. This drug does not seem to exert such an amount of desiccating effect on the corneal epithelium as does cocaine.

The list price of the drug is Rs. 2 per gramme, the cost of the same quantity of cocaine being Rs. 1-8. But considering that this drug is used in one-tenth of the strength of cocaine, it is, thus, really many times cheaper than cocaine. Compared with novocaine and ethocain also, it is cheaper for local anaesthesia, as for this purpose too it is used in one-tenth of the strength in which these drugs are used.

In the matter of resisting the effects of repeated sterilization, I had a striking demonstration of the advantage this drug has over cocaine. About two drachms of the solution were left after use and this happened to be sterilized day after day for over six weeks, the bottle having been left in the sterilisable set with other solutions. Subsequently, the solution was used on two cases for instillation and anaesthesia was perfect.

The solution can be prepared in plain distilled water but the makers recommend physiological saline as the solvent. I have found that the latter is more satisfactory. If there is any trace of alkali in the solvent, the solution of Pantocain becomes slightly cloudy, but this in no way interferes with the action of the drug. This drug is entirely free from the toxic effects of cocaine and is a very safe one to use.

Taking into consideration its cheapness, freedom from toxicity and absence of dehydrating effect on the cornea, I am of opinion that this drug can very well replace cocaine, and novocain or ethocain almost, if not quite, completely in ophthalmic practice.

Yours, etc.,

C. V. KRISHNASWAMI,

CAPTAIN, A.I.R.O.

M.B., B.S. (Mad.), D.O.M.S. (Lond.), F.R.C.S.E.,

Honorary Ophthalmic Surgeon.

GOVERNMENT HEADQUARTER HOSPITAL,
MADURA,

14th December, 1932.

Service Notes

APPOINTMENTS AND TRANSFERS

BREVET-COLONEL G. D. FRANKLIN, C.I.E., O.B.E., K.I.S., on return from leave, resumed charge of the duties of the Residency Surgeon, Hyderabad, with effect from the forenoon of the 9th December, 1932.

Lieutenant-Colonel A. D. Stewart was appointed temporarily as Director, All-India Institute of Hygiene and Public Health, Calcutta, with effect from the 1st January, 1932, and is confirmed in that appointment, with effect from the 23rd December, 1932.

Lieutenant-Colonel A. J. H. Russell, C.B.E., is appointed to officiate as Deputy Director-General, Indian Medical Service, with effect from the 1st January, 1933.

The services of Lieutenant-Colonel E. S. Goss, M.C., officiating Deputy Director-General, Indian Medical Service, are placed at the disposal of the Army Department, with effect from the 1st January, 1933.

Major J. Rodger, M.C., an Agency Surgeon, on return from leave, is posted as Civil Surgeon, Sibi, with effect from the forenoon of the 20th October, 1932. (The previous notification dated 10th November, 1932, on the subject is hereby cancelled.)

The services of Major P. A. Dargan are placed permanently at the disposal of the Government of the Punjab, with effect from the 17th April, 1931.

The services of Major G. H. Fraser are placed at the disposal of the Government of Burma for appointment as Superintendent, Mental Hospital, Tadagale, Rangoon, with effect from the 31st December, 1932.

The services of Captain H. S. Waters are placed temporarily at the disposal of the Government of Bombay, with effect from the forenoon of the 5th December, 1932.

Captain E. A. Y. Mackcown is appointed to officiate as ex Officer, Saugar Cantonment, in addition to his ordinary duties, *vice* Captain A. S. Sullivan, M.C. Dated 2nd December, 1932.

RETIREMENTS

Colonel W. R. J. Scroggie, C.I.E. Dated 23rd January, 1933.

Lieutenant H. Hannesson relinquishes his probationary appointment, 30th November, 1932.

Notes

THE ANNALS OF THE TOMARKIN FOUNDATION

The *Annals* of the Tomarkin Foundation, which is an international institution run very much on the lines of the Rockefeller Foundation, only on a smaller scale, are published quarterly. The range of subjects of the papers that are published in these *Annals* is a comprehensive one, but the majority of the papers report investigations that have a very practical application in the treatment and diagnosis of disease. Most of the papers in the number we have received are written in German, but a few are in French. Contributions from a number of well-known workers are included; for example there is a paper by Besredka on local vaccine therapy in intestinal infections, one by Calmette on the filterable elements in the virus of tuberculosis, one by Sachs on the problems of serum diagnosis, and one by Hauns Alexander on the work therapy in lung conditions.

The *Annals* are well printed on a good quality of paper, and should be in every comprehensive medical library.

The price of the publication is M. 16 annually, and the publisher is Georg Thieme, Leipzig.

MYCOZOL

Mycozol ointment contains chlorctone (chlorbutanol) 5 per cent., salicylic acid 4 per cent. and mercury salicylate 4 per cent., together with aromatics. The method utilized in its manufacture, and the nature of the base, results in a smooth, adhesive ointment that is rapidly absorbed by the skin, bringing the active ingredients into intimate contact with the deeper layers and preventing saturation of the dressings.

Mycozol is an effective remedial agent for the treatment of a number of skin lesions, classed under the general term 'epidermomycosis' and commonly referred to as 'foot itch', 'athletes' foot itch', 'swimmers' itch', 'jockey-strap itch', 'dhubie itch', and 'ringworm of feet'.

It is estimated that 50 to 75 per cent. of adults have some degree of fungus affection, particularly of the hands, feet, groin, axillæ, breast. In tropical countries this percentage is much higher; it would be no exaggeration to place it at 90 per cent.

It is generally agreed that in the treatment of epidermomycosis the best results are produced when a keratolytic, anti-pruritic and anti-parasitic ointment is chosen. With this in mind, Mycozol was developed, and successful clinical application warrants its extended use in all skin affections caused by the genus epidermophyton. Mycozol is non-irritating. It produces rapid maceration and the separation or peeling of the horny layers of the epidermis (Keratolysis), thus exposing the fungi to its inhibitive, possibly curative, action.

Mycozol is used to best advantage in the following manner, especially in the treatment of epidermophytosis of the hands and feet. This routine is modified somewhat in handling lesions in the region of the groin and the axillæ.

Scrub the affected area with a small, soft-bristled brush, using warm water and a thick lather of some germicidal soap (e.g., Neko 1 per cent.) or tincture of green soap. A soft tooth brush is suitable for the purpose.

After scrubbing, dry the parts with a soft cloth.

Apply alcohol and allow this to evaporate in the air until the parts are dry.

Mycozol is thoroughly rubbed into the affected parts, and a liberal excess allowed to remain on the skin; the area is then covered with cotton or gauze, held in place by a bandage and left on overnight.

The Mycozol is removed in the morning by means of talcum powder, before bathing.

Repeat the procedure each night until desquamation is complete and no more bullae, vesicles, papules or macules are observed.

Caution.—In dressing the affected areas, as small an amount of Mycozol as possible should be allowed to come in contact with the normal skin; and in any location where chafing might result from attrition of opposing surfaces, if Mycozol is required, it should be applied sparingly.

Packages.—Mycozol is supplied in one-ounce tubes, each tube provided with a label that can be slipped off for convenience in prescribing. The tubes are marketed in individual cartons, twelve to the package.

ELECTRO-MEDICAL APPARATUS

WATSON & SONS (Electro-Medical) are known throughout the world as manufacturers of high-class electro-medical apparatus. Their latest catalogue shows a very wide range of modern apparatus for use in almost all special branches of medical science. The appliances in which they specialize are diathermy and cautery apparatus. It is difficult to make a selection for special mention, but the 'Sunic' junior diathermy apparatus has many features which should appeal to the medical man in this country; the price complete is £55, where an alternating current is available. The makers claim that it is an instrument of robust construction and of reliability in performance. The spark gap is of a special type with large contacts, so that the output is smooth and the machine is capable of continuous work. Other special features which they claim are:—

1. New type cabinet, white enamel with glass top.
2. Vertical mounting of controls—conveniently manipulated.
3. All parts easily accessible.
4. Vacuum impregnated mica condenser in porcelain case.
5. Potentiometer control giving smooth variation of output, zero maximum.
6. Thermo-couple ammeter.
7. Smooth output as follows:—

Load resistance	Current	Watts (I ² R)
25 ohms.	2.9 amps.	210
50 "	2.1 "	220
100 "	1.45 "	210
200 "	1.0 "	200
8. Short circuit current of the order of 6 ampères.
9. Improved 'Sunic' spark gap with 9/16 inch diameter contacts—two contacts, four points.

Their infra-red lamp is one that should be useful to practitioners, and again the price is moderate. This lamp consists of a special high-power evacuated bulb, giving a powerful output of infra-red rays. It can be used singly for infra-red therapy or in conjunction with the mercury vapour lamp.

The bulb is mounted in a double-walled reflector, 18 inches in diameter, designed to give ample ventilation. A wattage of 1,500 can be employed without undue risk of damage to the bulb. The reflector is hung on a wall bracket with counterweight arrangement, which allows of ample movement in all directions. A red glass screen, made in strips to avoid breakage due to expansion, can be fitted to the hood.

The firm's office in India is at Commercial House, Currimbhoy Road, Ballard Estate, Bombay, and the head office is Sunic House, Parker Street, Kingsway, London, W.C.2.

RADIOGRAPHIC EXAMINATION OF THE GALL-BLADDER

For the radiographic examination of the gall-bladder there are two useful products, 'Stipolae' brand tetra-iodophenolphthalein and 'Wellcome' brand sodium

tetra-iodophenolphthalein. The 'Stipolae' brand tetra-iodophenolphthalein product is supplied in two tubes containing 'Stipolae' sodium tetra-iodophenolphthalein and 'Stipolae' acid mixture, respectively. 'Wellcome' brand sodium tetra-iodophenolphthalein is intended for use in intravenous administration.

Administration

The patient is given a 'mild' aperient—preferably castor oil—24 hours before the product is administered. A light meal (nothing at all afterwards) is taken at 6 P.M. on the following day, and at 9 P.M. the whole contents of the two tubes containing 'Stipolae' sodium tetra-iodophenolphthalein and 'Stipolae' acid mixture, prepared as directed, are given. Radiograms are taken at 9-30 A.M. and 12-30 P.M. next day. If a good shadow is obtained, a meal rich in fat, e.g., egg-yolks, which hastens the emptying of the gall-bladder, is given, and a third radiogram is taken at 3-30 P.M. If this radiogram shows the gall-bladder to be empty or nearly so, i.e., the shadow reduced in size, the gall-bladder is probably normal. If it has not emptied, or the shadow is very indistinct, further investigation of the patient is necessary. In a normal gall-bladder, a shadow is visible 12 hours after administration of the dye; after 15 hours it is denser and usually smaller; two to three hours after the meal of fat, the shadow should be absent or much reduced.

These products are issued by Burroughs Wellcome & Co., of Snow Hill Buildings, London, E.C.1, and Cook's Building, Hornby Road, Bombay.

TYCOS SCIENTIFIC INSTRUMENTS

THE writings of the early philosophers responsible for experiments which ultimately led to discoveries resulting in the birth of the barometer include those of Anaxagoras (500 to 428 B.C.), Empedocles (504 to 443 B.C.), the more definite ideas of Aristotle (385 to 322 B.C.), and the concepts of Seneca (54 B.C. to 39 A.D.), the last-named being very familiar with the 'Meteorologica' of Aristotle.

After about the first century the prosecution of science ceased, and it was not until the era of Galileo, A.D. 1613, that anything definite is recorded as to further progress. He commended to his pupil, Torricelli (A.D. 1645), that his experiments be continued, but Torricelli died before the discovery was fully completed.

Pascall (A.D. 1648) discovered that atmospheric pressure varied at different elevations, and thus demonstrated the theory of altitude measurements. It was not until A.D. 1665 that the barometer received its name, when an unsigned note (attributed by some to Robert Boyle), appeared in the *Philosophical Transactions* referring to a 'new kind of barometer which may be called statical'.

Dr. Hooke (A.D. 1686) produced the first type of mercurial weather barometer of the 'wheel type'.

Conté (A.D. 1798) was responsible for the first metal barometer known as the 'Aneroid', derived from the Greek words meaning 'without fluid'.

Vidi (A.D. 1841) improved on the aneroid of Conté by designing an aneroid barometer with a corrugated vacuum box which gave a greater elasticity to the movement.

Sir G. B. Airy, K.C.B. (A.D. 1801 to 1881) compiled a scale of feet measurements to match the scale of inches of pressure on the barometer.

Admiral Fitzroy, R.N., F.R.S. (A.D. 1805 to 1865), was responsible for weather indications known to-day as 'Fitzroy words'.

This note is extracted from the catalogue of Short and Mason, Ltd. They are manufacturers of a very big range of meteorological and other scientific instruments; their Tycos 'Stormographs' are extensively used in this country. This catalogue contains descriptions of a number of instruments suitable for both domestic and scientific use. Their thermo-hygrometers are of a pattern which will appeal to the malariologist and the research worker.

The head office and factory of the firm are the Aneroid Works, Walthamstow, London, E.17, and their local agents are, L. H. Alliston & Co., Ltd., Clive Buildings, Calcutta.

NEOSALVARSAN

It has been brought to our notice that a small chemist firm in the Punjab is keeping and offering for sale a consignment of Neosalvarsan, which was not imported through our firm, the only legal channel for India, Burma and Ceylon. The packings bear French labels and do not show the usual batch-control number in four Roman capitals (e.g., VXL M, etc.) which, in the legally imported stocks, is always shown on the left hand side of the attached label on the packing box as well as on the label of the ampoule itself. Further, the packings from this consignment also do not possess the protective labels with the name of our firm.

The sample ampoule, which was sent to us, shows on the bottom of the packing box the number A-33925. From this we have been able to find out that the consignment left the factory of our manufacturers on the 12th December, 1912 (i.e., 20 years ago), and was sold to a customer in Constantinople. The content of the ampoule was found to give a very turbid solution of rather reddish tint, indicating thereby its absolute unfitness for use. It is not known to us how many ampoules of the contraband consignment are now being actually offered for sale; nor can we assert if all the packings thereof bear the same number, viz., A-33925.

However, we strongly warn the medical profession against accepting and using such contraband packings of Neosalvarsan. We should like to remind them once again that all genuine and legally imported packings of Neosalvarsan do invariably bear the batch-control number in Roman capitals, and are further guaranteed by the protective label round the packing having the well-known inscription:

'Specially manufactured for the tropics and packed for British India and Ceylon. Imported by Messrs. Havero Trading Co., Ltd., Calcutta, Bombay and Madras.'

Under the circumstances, we beg to declare that no responsibility or obligation whatever may be expected from our side, should any mishap occur by and through the use of such contraband packings of Neosalvarsan.

'Bayer-Meister Lucius,'
Havero Trading Co., Ltd.,

Pharmaceutical Dept.,
15, Clive Street,

P. O. Box 2122,
Calcutta.

ANTIPHLOGISTINE SUBSTITUTES

THE following notice has been sent to us by the manufacturers of Antiphlogistine:—

When a physician prescribes a product which his experience and skill has demonstrated to be the best treatment for some special condition, he has a right to that product—moreover, his patient is entitled to that product. Anything less than this will not suffice! Not only is substitution of a medical product, immoral, but the manufacturer or retailer who encourages the use of his own or other imitations is not only jeopardizing his reputation and standing, but is betraying the confidence of his clients.

Many cases are on record where substitutions made to look and smell like Antiphlogistine have caused much suffering, and instances are not rare where the actual life of the patient has been sacrificed through the use of inert and even dangerous substitutes.

Antiphlogistine, a scientific therapeutic remedy, is compounded to bring relief to suffering humanity—imitators deceive the suffering for a profit, often jeopardizing the health and life of those who are unable to recognize the fraud. Physicians should warn their patients and clients of the inert, harmful and dangerous substitutes which are now flooding India to be sold in place of the genuine Antiphlogistine.

Antiphlogistine cannot be successfully imitated—the process and laboratory apparatus for compounding, and the peculiar silicate of aluminium base obtained from privately-owned mines are available to none other than the Denver Chemical Manufacturing Company.

'SCIATAGO'

UNDER the above name, Messrs. Coates & Cooper, Ltd., 94, Clerkenwell Road, London, E.C. 1, have issued a preparation in dragées, stated to consist of phenol-quinolin-carboxylic acid, hexamethylene-tetramine, and glyccoll, a formula which has been used with success for some time on the Continent in the treatment of rheumatism, sciatica, and lumbago. The preparation is put up in tins each containing 40 dragées of 3 grammes each, the dose being two dragées twice daily after a light meal. Treatment should be continued for 2 to 3 weeks, and a second course may be prescribed after an interval of 2 weeks. The firm will be glad to send samples and literature upon request by members of the medical profession.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

As misunderstanding still appears to exist, we should like to point out again to our readers and advertisers that the "*Indian Medical Gazette*" is owned and published by Thacker's Press & Directories, Ltd. Hitherto, Thacker, Spink & Co., now in liquidation, have been the selling agents; this work is now being undertaken by Thacker's Medical Book Dept., Box No. 54, Calcutta.

AN ANALYSIS OF ONE HUNDRED AND FIFTY CASES OF ASTHMA

By HUGH W. ACTON, C.I.E.

LIEUTENANT-COLONEL, I.M.S.

Professor of Pathology and Bacteriology and Director
and

DHARMENDRA, M.B., B.S.

Assistant Research Worker,
Calcutta School of Tropical Medicine

THIS investigation was undertaken in order to find out the cause of the syndrome of asthma in each individual case so that a rational treatment could be given to each patient. In all, one hundred and sixty-one cases were investigated, of these only one hundred and fifty were included in the analysis; eleven cases were rejected as they were found to be cases of chronic bronchitis alone. The investigation included physical examination of the patient, blood examination as regards the total leucocytes, total eosinophiles and Arneth's count, smear and cultural examinations of the sputum, as well as examinations of the stools for *Entamoeba histolytica*, ova of helminths and pathogenic bacteria. Dermal tests were done with extracts made from the hairs and feathers of common animals and from common foods. Usually a von Pirquet's test was done and a skiagram was taken of the chest. Where indicated, expert advice was obtained on the state of the nose, throat and para-nasal sinuses.

Clinically the cases could be divided into three groups:—

(1) Cases due to chronic bronchitis, bronchiectasis and other chronic lesions of the lung. In these cases there was no evidence of allergy, and the age of onset of the disease was usually above twenty years (in 50 per cent. of the cases above thirty years). This group included seventy-nine of our cases, i.e., about 53 per cent. of all the cases.

(2) Bronchial cases in which Gram-negative bacilli were present in smears made from the sputum and were also isolated from the sputum in cultures. This group formed a clinical entity because of the presence of these bacilli and the associated high blood eosinophilia in contrast to the usually low blood eosinophilia in group (1). This group includes twenty-seven of our cases, i.e., 18 per cent. of the total cases. These cases have been described by us in a separate paper.

(3) This group contains three types of case. Firstly, cases due to some external allergen, secondly, cases due to some allergen from the gut, and, thirdly, those bronchial cases which were not definitely allergic but in which there was some evidence of allergy in the shape of

heredity, early age of onset, or positive dermal tests. For purposes of simplification we have included all these three types in one group which we have called the allergic group. This group includes forty-four cases, i.e., about 30 per cent. of the total cases. The distribution of these allergic cases amongst Indians and Europeans is rather interesting and will be referred to later in this paper.

THE ANALYSIS.

(1) *The total leucocytes, the number of polymorphonuclears and eosinophiles per cubic millimetre of blood.*—The total leucocyte and eosinophile counts are important from the diagnostic point of view. This question has been discussed by us in a separate paper. The Gram-negative-bacilli cases and the allergic cases show a high blood eosinophilia in contrast to the usually low figures in bronchial cases. No information of any value was obtained from the polymorphonuclear count.

(2) *The Arneth's count which is of great help in differentiating the bronchial cases from the allergic.*—In the bronchial and Gram-negative-bacilli cases there is usually a marked shift to the left, in true allergic cases the count is more or less unaffected, but in bronchial cases showing some evidences of allergy there is also a marked shift to the left. If we express the Arneth's count in terms of Arneth's index (the sum of the first two columns plus half of the third column) we find that:—

(a) In sixty-nine out of seventy-nine bronchial cases, the Arneth's index was above seventy.

(b) In nineteen of twenty-seven Gram-negative-bacilli cases, the Arneth's index was above seventy.

(c) In twenty out of thirty-seven allergic cases the Arneth's index was below seventy; only in seventeen cases it was above seventy and these seventeen cases were bronchial cases with allergy.

(3) *The total eosinophile count and Arneth's count considered together.*—We find that:—

(i) A low eosinophile count with a marked shift in Arneth's count to the left is usually found in bronchial cases.

(ii) A low eosinophile count with little or no shift in Arneth's count is found in some allergic cases (without high eosinophilia).

(iii) A high eosinophile count with a marked shift in the Arneth's count to the left is found in the Gram-negative-bacilli cases, in the mixed type of bronchial and allergic, and in some bronchial cases having a high eosinophilia.

(iv) A high eosinophile count with little or no shift in Arneth's count is usually found in allergic cases.

(4) *Heredity.*—Forty cases gave a history of inheritance. A history of heredity is more common in the Gram-negative-bacilli cases than in the other types. There is no correlation between heredity and blood eosinophilia, sputum

eosinophilia, or age of onset of the disease as is shown in table I. eosinophiles varied from a small percentage of the cellular exudate to nearly all the cells being

TABLE I

	Total number of cases	Cases giving history of inheritance	Blood eosinophilia in cases showing heredity	Sputum eosinophilia in cases showing heredity	Age of onset in cases showing heredity
Bronchial cases	79	15	3 cases eosinophiles under 250 per c.mm. 4 cases eosinophiles between 250 and 500 per c.mm. 3 cases eosinophiles between 500 and 750 per c.mm. 3 cases eosinophiles between 750 and 1,000 per c.mm. 2 cases eosinophiles above 1,000 per c.mm.	11 cases no eosinophiles in sputum. 1 case majority of the cells eosinophiles. 2 cases a few eosinophiles. 1 case there was no sputum.	2 cases started in childhood. 1 case started between 5 and 10 years. 1 case started between 11 and 15 years. 1 case started between 16 and 20 years. 4 cases started between 21 and 30 years. 6 cases started above 30 years.
Gram-negative-bacilli cases.	27	13	1 case eosinophiles under 750 per c.mm. 3 cases eosinophiles between 750 and 1,000 per c.mm. 9 cases eosinophiles ranging from 2,000 to 11,000 per c.mm.	8 cases no eosinophiles in sputum. 5 cases eosinophiles in sputum.	2 cases started between 11 and 15 years. 2 cases started between 16 and 20 years. 6 cases started between 21 and 30 years. 3 cases started above 30 years.
Allergic cases	44	12	2 cases eosinophiles under 250 per c.mm. 2 cases between 250 and 500 per c.mm. 2 cases eosinophiles between 500 and 1,000 per c.mm. 2 cases eosinophiles under 3,000 per c.mm. 2 cases eosinophiles under 4,000 per c.mm. 2 cases eosinophiles under 9,000 per c.mm.	5 cases no eosinophiles in sputum. 4 cases eosinophiles in sputum. 3 cases no sputum.	5 cases started in childhood. 1 case started between 5 and 10 years. 1 case started between 11 and 15 years. 1 case started between 16 and 20 years. 2 cases started between 21 and 30 years. 2 cases started above 30 years.
TOTAL	150	40	5 cases under 250 per c.mm. 6 cases between 250 and 500 per c.mm. 5 cases between 500 and 750 per c.mm. 7 cases between 750 and 1,000 per c.mm. 17 cases above 1,000 per c.mm.	24 cases no eosinophiles in sputum. 12 cases eosinophiles in sputum. 4 cases no sputum.	7 cases started in childhood. 2 cases started between 5 and 10 years. 4 cases started between 11 and 15 years. 4 cases started between 16 and 20 years. 12 cases started between 21 and 30 years. 11 cases started above 30 years.

(5) *Sputum eosinophilia*.—Thirty-six cases had eosinophiles in the sputum, the number of eosinophiles. Table II shows the incidence of sputum eosinophilia amongst the three groups.

TABLE II

	Total number of cases	Cases showing eosinophiles in sputum	Blood eosinophilia in cases showing sputum eosinophilia	Heredity in cases showing sputum eosinophilia
Bronchial cases ..	79	16	5 cases eosinophiles below 250 per c.mm. 6 cases eosinophiles between 250 and 500 per c.mm. 1 case eosinophiles under 2,000 per c.mm. 1 case eosinophiles under 4,000 per c.mm.	Only 3 cases show heredity.
Gram-negative-bacilli cases.	27	8	1 case eosinophiles under 750 per c.mm. 1 case eosinophiles under 1,000 per c.mm. 1 case eosinophiles under 3,000 per c.mm. 1 case eosinophiles under 5,000 per c.mm. 1 case eosinophiles under 6,000 per c.mm. 1 case eosinophiles under 7,000 per c.mm. 1 case eosinophiles under 10,000 per c.mm. 1 case eosinophiles under 11,000 per c.mm.	Only 5 cases show heredity.
Allergic cases ..	44	12	2 cases eosinophiles under 500 per c.mm. 2 cases eosinophiles under 750 per c.mm. 1 case eosinophiles under 1,000 per c.mm. 2 cases eosinophiles under 2,000 per c.mm. 1 case eosinophiles under 3,000 per c.mm. 1 case eosinophiles under 6,000 per c.mm. 1 case eosinophiles under 7,000 per c.mm. 2 cases eosinophiles under 12,000 per c.mm.	Only 4 cases show heredity.
TOTAL ..	150	36	5 cases eosinophiles under 250 per c.mm. 8 cases eosinophiles between 250 and 500 per c.mm. 3 cases eosinophiles under 750 per c.mm. 5 cases eosinophiles under 1,000 per c.mm. 3 cases eosinophiles under 2,000 per c.mm. 2 cases eosinophiles under 3,000 per c.mm. 10 cases eosinophiles above 3,000 per c.mm.	Only 13 cases show heredity.

TABLE III

	Total number of cases	NUMBER OF CASES STARTING					
		in infancy and childhood	between 5 and 10 years of age	between 11 and 15 years of age	between 16 and 20 years of age	between 21 and 30 years of age	after 30 years of age
Bronchial cases ..	79 Age of onset not known in 1 case.	3 (H in 2)	4 (H in 1)	3 (H in 1)	3 (H in 1)	27 (H in 4)	38 (H in 6)
Gram-negative-bacilli cases.	27	4 (H in 2)	6 (H in 2)	12 (H in 6)	5 (H in 3)
Allergic cases ..	44 Ages of onset not known in 6 cases.	12 (H in 5)	2 (H in 1)	4 (H in 1)	4 (H in 1)	7 (H in 2)	9 (H in 2)
TOTAL ..	150 Ages of onset not known in 7 cases.	15 (H in 7)	6 (H in 2)	11 (H in 4)	13 (H in 4)	46 (H in 12)	52 (H in 11)

H = history of inheritance.

The table also shows that there is no correlation between the sputum eosinophilia and blood eosinophilia or between sputum eosinophilia and heredity.

(6) *Age of onset of the disease.*—Table III shows the ages of onset in the three groups of

(8) *Von Pirquet's test.*—This was performed in ninety-three cases with forty-seven negative and forty-six positive results. Table V shows these results. It will be noted that the test was positive in more than half of the bronchial cases tested, both the bronchial and Gram-

TABLE IV

	Total number of cases	Number of cases in which dermal tests were done	RESULTS		Positive	Particulars of positive tests
			Negative	Doubtful		
Bronchial cases	79	67	57	3	7	4 cases positive to bacterial extracts. 3 of these cases eosinophiles under 500 per c.mm. 1 of these cases eosinophiles under 6,000 per c.mm. 1 case positive to grass pollens. Eosinophiles 750 per c.mm. 1 case positive to horse-hair. Eosinophiles 750 per c.mm. 1 case positive to cattle-hair. Eosinophiles 3,000 per c.mm.
Gram-negative-bacilli cases.	27	25	22	..	3	1 case positive to cattle-hair. Eosinophiles 10,000 per c.mm. 1 case positive to grass pollens. Eosinophiles 5,000 per c.mm. 1 case positive to foods. Eosinophiles 6,000 per c.mm.
Allergic cases	44	41	14	9	18	8 cases positive to different foods. 10 cases positive to feathers, hairs, dust, etc. In half of the cases the blood eosinophiles were below 1,500 per c.mm., while in the other half they were above this figure.
TOTAL ..	150	133	93	12	28	

cases. It will be seen that the majority of the bronchial cases start after twenty years of age, the Gram-negative-bacilli cases start rather earlier, and most of the allergic cases start very early; eighteen out of thirty-eight started before fifteen years of age. The table also shows that there is not much correlation between heredity and the age of onset.

(7) *Dermal tests.*—The results of the dermal tests are shown in table IV. It is evident from the table that in the bronchial and Gram-negative-bacilli cases the dermal tests are of no value. In allergic cases, where the trouble is due to emanations from hair, feathers or dust, these tests are of value, but in allergic cases dependant on some pathological condition of the gut the dermal tests are valueless. The tests are either all negative or all positive. The table also shows that there is some correlation between positive dermal tests and the high blood eosinophilia in bronchial and Gram-negative-bacilli cases.

negative groups, and in only 4 out of 17 allergic cases.

(9) *Evidence of tuberculosis.*—Clinical or radiological evidence of pulmonary tuberculosis was found in eighteen cases, fifteen of these were included in the bronchial group and three in the Gram-negative-bacilli group. Table VI shows the distribution of these cases and their relation with the Von Pirquet test and blood eosinophilia.

(10) Only in one case there was some other co-existing allergic manifestation present (allergic dermatitis).

(11) Amongst the allergic group there were four cases in which the attacks of asthma were associated with the locality, the patients being free from attacks when they kept away from that particular place. No such association was seen amongst the bronchial or Gram-negative-bacilli cases.

(12) In three cases some special food was responsible for the attacks or made the attack worse.

(13) There were twenty-two females in this

pneumonia and chronic bronchitis. A history of previous pneumonia was more common in the Gram-negative-bacilli cases than in bronchial cases; it was much less common in allergic

* These cases are mostly bronchial cases with some evidence of allergy.

(16) The ether test for proteoses was done in seventy-five cases with sixty-eight positive and seven negative results, as shown in table IX.

(17) Skiagram of the chest.—In the allergic cases the x-ray picture was as a rule quite normal (figure 1). The bronchial and Gram-

clavicle (figures 3 and 4). Amongst the bronchial cases apart from the healed lesions evidence of active disease was found in five cases; out of these there was an early lesion in one case (figure 5) and well advanced lesions in four cases (figures 6, 7 and 8).

PLATE III

Fig. 1.—Skiagram from a case secondary to gut infection. The lungs are quite normal.

Fig. 2.—Skiagram from a bronchial case. Increased fibrosis and enlarged hilus glands.

Fig. 3.—Skiagram from a bronchial case. A calcified focus in the right upper lobe.

Fig. 4.—Skiagram from a bronchial case. Two calcified areas in the left upper lobe.

PLATE IV

Fig. 5.—Early tuberculous focus in right lung $\frac{1}{4}$ inch below the apex.

Fig. 6.—Right apex extensively infiltrated.

Fig. 7.—Extensive lesion of right upper and middle lobes with extension into lower lobe. Early disease left side, lower part of upper lobe.

Fig. 8.—Complete consolidation of left upper lobe.

(18) *Therapeutic test.*—Attacks in most of the bronchial cases were controlled by A. P. C. powders (aspirin grs. v, phenacetin grs. iii, and caffeine grs. iii), some of the cases required injections of morphia. The Gram-negative-bacilli cases responded both to A. P. C. and adrenalin injections, the adrenalin being on the whole more useful. The allergic cases did well with adrenalin injections.

European cases 13 out of 35 and on the Indian side only 31 were diagnosed as due to allergy.

(ii) Out of the thirteen cases of allergy in Europeans ten were due to external excitants and three to gut infections; amongst the Indians out of thirty-one cases only twelve were due to external excitants and nineteen to gut infections. So that the European cases are more sensitive to external allergens than the Indian

TABLE X

	Total number of cases	Total number of cases showing allergy	CASES SHOWING ALLERGY		Evidences of allergy in cases probably due to external excitants
			Number of cases in which the allergy is due to gut conditions	Number of cases in which the allergy is due to external excitants	
Europeans	35	13	3	10	3 cases. Positive dermal tests—association with the excitant brings on attack. 1 case. Heredity—positive dermal tests—onset at early age. 2 cases. Positive dermal tests. 2 cases. Onset at early age (3 and 6 years)—doubtful dermal tests. 1 case. Starting in infancy. 1 case. Heredity—onset at comparatively early age.
Indians ..	115	31	19	12	1 case. Positive dermal test—association with excitants brings on attack—the patient successfully desensitised with repeated small doses of the excitant. 4 cases. Heredity—asthma at early age. 2 cases. Asthma starting at early age. 1 case. Heredity—positive dermal tests. 3 cases. Positive dermal tests. 1 case. Doubtful dermal tests.

(19) *Allergic cases.*—The distribution of allergic cases amongst Indians and Europeans is rather interesting and is put down in the above table.

A perusal of the above table brings out the following points.

(i) Allergic cases are more common amongst Europeans than amongst Indians; of the

cases amongst whom only 10 per cent. are sensitive to external allergens. On the other hand few of the Europeans were sensitive to allergens from the gut whilst 19 out of the 31 Indian allergic cases were sensitive to allergens from the gut.

(iii) When the evidence of allergy in the cases sensitive to external excitants is analysed

it is found that out of ten of the European cases three were proved to be definitely allergic by a positive dermal test and the fact that they gave a history that the excitant brings on the attack. In seven cases the presence of the allergy was presumed from a history of inheritance, or a positive dermal test or the disease started in childhood. Amongst the Indian cases, allergy was definitely established only in one case out of twelve, in others (who were really bronchial cases) the

organisms isolated from the stools, depending on whether the case was one of amœbic infection, hookworm disease or some post-dysenteric lesion of the gut. The allergic cases when found to be sensitive to an external allergen were advised to avoid the particular excitant and in this group one case was successfully treated by repeated injections of the excitant (this case was sensitive to seed dust and was desensitised by repeated injections of the sterile extract made from the dust). The

TABLE XI

TOTAL ..	150	98	57 (six relapsed).	16	20	5	

presence of allergy was presumed from the history of inheritance, a positive dermal test or the early age of onset. This fact further demonstrates the rarity of asthma of allergic origin amongst Indians. In this connection it is interesting to note that Coca, Deibert and Menger (1922) found that the American Indian did not suffer much from these allergic phenomena, asthma and urticaria as compared with the white races. An experimental study of the occurrence of serum disease in twenty-six volunteers, pure-blooded American Indians—indicates that the Indian race was much less susceptible to that condition than the white races.

(20) The results of treatment are given in table XI.

The bronchial cases were treated with a course of autovaccine prepared from the sputum, the Gram-negative-bacilli cases were treated with a vaccine made from that organism. It will be seen that the benefit derived from the vaccine treatment in both the groups is about the same. The allergic cases of gut origin were treated with emetine, carbon tetrachloride or autogenous vaccine prepared from the pathogenic

mixed bronchial and allergic cases were treated with autogenous vaccines made from the sputum as in bronchial cases.

GRAM-NEGATIVE-BACILLI ISOLATED FROM THE SPUTUM IN CASES OF ASTHMA

By HUGH W. ACTON, C.I.E.

LIEUTENANT-COLONEL, I.M.S.

Professor of Pathology and Bacteriology and Director and

DHARMENDRA, M.B., B.S.

Assistant Research Worker,
Calcutta School of Tropical Medicine

Introduction.—Walker (1919) recovered a Gram-negative-bacillus from the sputum of one out of 74 cases of asthma; the organism resembled the coli type of bacilli in its sugar reactions. Rackemann (1920) investigating the bacteriology of the sputum in 40 cases of asthma isolated a Gram-negative-bacillus in two cases. Rackemann and Graham (1923) in the sputa

from 29 cases of asthma found a Gram-negative-bacillus predominating in one case. Thomas, Famulener and Touart (1924) found a Gram-negative-bacillus in 30 out of 180 cases of asthma. Noranha (1926) reported two cases of asthma successfully treated with a vaccine made from Gram-negative-bacilli isolated from the sputum. Eyre (reported by Knott, 1929) was the first to call special attention to the occurrence of these Gram-negative-bacilli and the fact that by vaccine injection or intracutaneous testing patients could often be shown to be specially sensitive to them. He found that the bacillus grew well at 22°C. and called it the 'asthma bacillus'. Knott, Oriel and Witts (1930) isolated in 48 cases out of 132 sputa examined these Gram-negative-bacilli by Eyre's technique, i.e., incubating the sputum on blood-agar plates at 22°C. Knott and Oriel (1930) considered that these bacilli might be producers of a histamine-like substance which is present in many asthmatic sputa.

SIGNIFICANCE OF THE BACILLUS

(1) *Histamine production*.—Knott, Oriel and Witts (1930) studied 22 strains of these bacilli in detail and found 10 strains to be histamine producers. Knott and Oriel (1930) obtained a histamine-like effect from extracts of various asthmatic sputa. Referring back to the bacteriology of these particular sputa they found that many showed in the bronchial plugs numerous Gram-negative-bacilli. The broth culture extracts of these bacilli gave a histamine-like effect similar to that obtained from the sputum itself. They think that the histamine-like substance demonstrable in the plugs may have arisen as a result of the growth of these bacilli within the small bronchial tubes. In this connection it is interesting to note that Harkavy (1930) had already shown the presence of a spasm-producing substance in asthmatic sputa. Oriel (1932) considers that the local production of histamine in the bronchi in addition to causing contraction of the plain muscle surrounding the bronchi would also tend to increase the permeability of the epithelium lining the bronchioles, and facilitate the entrance of foreign proteins and possibly bacteria. Professor McDowall (1932) speaking at the first International Congress on Asthma drew attention to this local production of bronchospasm through the liberation of histamine in the bronchi by these bacilli.

(2) *Cutaneous sensitivity to emulsion of the organism*.—Knott, Oriel and Witts (1930) found that skin tests made with emulsion of these organisms gave positive results in 74 per cent. of patients from whom they were isolated and in only 11 per cent. of patients in whom they were absent. In cases tested for cutaneous sensitivity to emulsions of cocci obtained from their asthmatic plugs no positive reactions were obtained.

(3) We have shown that in asthmatic cases with Gram-negative-bacilli infection there is usually a very high blood eosinophilia and that they form a separate clinical group.

(4) Knott, Oriel and Witts (1930) found eosinophiles in the sputum in seven-eighths of his cases with Gram-negative-bacillus infection while only one half of other cases showed eosinophiles in the sputum, i.e., out of 48 cases with Gram-negative-bacillus 42 showed eosinophiles in the sputum and 6 did not; of the remaining 84 cases only 43 showed eosinophilia in the sputum and 41 did not.

We do not find any correlation between Gram-negative-bacillus infection and sputum eosinophilia; to this point we shall refer later.

In a series of 150 cases we obtained Gram-negative bacilli in 27 cases, i.e., 18 per cent. of our cases.

DESCRIPTION OF THE BACILLUS

Morphology.—Non-sporing, short thick rods, straight or slightly curved, occurring singly, in pairs or in small chains. Very pleomorphic in cultures, when diplococcal or very long filamentous forms are seen.

Motility.—Non-motile.

Staining reactions.—Gram-negative, non-acid-fast, capsule not seen.

Cultural characters.—Grows well on ordinary media at our room temperature (27° to 32°C.) and at 37°C. Cultures kept in the cold-room (21° to 23°C.) did not grow.

Gelatin stab (with 1 per cent. agar):—No surface growth. Growth along stab. No liquefaction.

Agar slant:—Fine opaque colonies with transmitted light, which coalesce together to make a streak. Growth moderately profuse.

Blood-agar slant:—No hæmolysis, fine transparent growth.

Serum:—No visible growth. Smear shows scanty growth.

Nutrient broth:—Slight turbidity with a watered-silk appearance, deposit at the bottom.

Potato:—No visible growth, on staining short diplococcal and bacillary forms are seen.

Sugars:—No gas is formed in any of the sugars tested, acid is usually formed in glucose, levulose, galactose, maltose, saccharose and dextrin. Usually no acid is formed in lactose, dulcitol, salicin and inulin. Mannite is usually fermented with the production of acid, but when the strain is kept for some time the subcultures do not attack mannite. Sugar reactions for the 15 strains studied are given in table I.

Litmus milk:—Usually unchanged. Slight acidity in one case and acid and coagulation in another—in this case lactose was also fermented with production of acid.

Pathogenicity.—Non-pathogenic to mice, rats and rabbits by intraperitoneal and intravenous injections.

Heat.—Heating at 50°C. for 15 minutes kills the organisms.

Histamine production.—This was studied in 8 strains with negative results. As we obtained negative results with cultures in ordinary broth,

fermentation, and is allied to the coli type of bacilli. No gas is produced in any sugar by any of the strains studied by us.

TABLE I.

A statement showing the sugar reactions and motility of 15 strains of Gram-negative-bacilli (reactions in laevulose, galactose, arabinose, inulin and dextrin were studied in only 5 strains).

No.	Motility	Lactose	Glucose	Maltose	Saccharose	Mannite	Dulcite	Salicin	Litmus milk	Lævulose	Galactose	Arabinose	Inulin	Dextrin

A = acid in sugar media.
Ac = acid and coagulation.

As = slight acid.
— = non-motile.

O = no acid or gas in sugar media.

cultures made in serum broth and Martin's broth were also tested with negative results.

When we come to compare the Gram-negative-bacilli isolated in our study to those isolated by others we note that:—

1. No description is given of the organisms except by Walker and Knott.

3. The 22 strains studied by Knott showed a great variation as regards the sugar reactions, which are shown in a compressed form in table II.

His 22 strains can be divided into two groups—non-lactose fermenters and lactose fermenters. Non-lactose fermenters can be further divided

TABLE II.

		Lactose	Glucose	Saccharose	Maltose	Mannite	Dulcite	Litmus milk

A = acid.

AG = acid and gas.

Alk. = alkaline.

2. The one strain isolated by Walker produced acid and gas in the sugars undergoing fermentation, and is allied to the coli type of bacilli. No gas is produced in any sugar by any of the strains studied by us.

glucose. Lactose fermenters can similarly be divided according to whether they produce (A) or (A & G) in lactose.

It will be seen while our strains differ widely from Knott's, all of our strains resemble each other rather closely, thus leaving out the lactose-

LACTOSE

For comparison we give the sugar reactions in a compressed table for the 15 strains studied by us (table III).

We see that :—

(1) Fourteen strains out of the 15 are non-lactose fermenters.

(2) The one lactose fermenter produces only acid in lactose and other sugars, amongst Knott's strains there is one strain that is similar to this but differing in not fermenting saccharose and mannite and in producing only acid in milk while our strain produces acid and coagulation.

fermenting strain and the one non-lactose-fermenting strain not fermenting glucose we find that :—

(a) All the 13 strains ferment glucose and saccharose, and none of them has any action on milk.

(b) All but 2 ferment maltose and all but 5 ferment mannite.

(c) Dulcitate and salicin are not as a rule attacked; only one strain ferments dulcitate and the two strains that do not ferment maltose ferment salicin.

TABLE III.

		Lactose	Glucose	Maltose	Saccharose	Mannite	Dulcitate	Salicin	Litmus milk
	1 strain ..	—	—	As	As	As	—	—	As
13	2 strains ..	—	A	—	A	A	—	A	—
	1 strain ..	—	A	A	A	A	A	—	—
	6 strains ..	—	A	A	A	A	—	—	—
	4 strains ..	—	A	A	A	—	—	—	—
	1 strain ..	A	A	A	A	A	—	A	Ac

A = acid.

As = slight acid.

Ac = acid and coagulation.

— = no reaction.

(3) Amongst the 14 non-lactose fermenters there is one strain which does not attack glucose and produces very slight acid in other sugars.

(4) The remaining 13 non-lactose fermenters produce acid in glucose and belong to the first sub-group in Knott's strains. However, they differ from his 6 strains in this sub-group as under :—

(a) None of our strains produce any change in litmus milk; 4 of his strains make it alkaline and two acid.

(b) All of our strains ferment saccharose; none of his 6 strains attack this sugar.

(c) Eight of our strains ferment mannite; none of his six strains attack this sugar.

(d) Eleven of our strains ferment maltose; only one of his strain ferments this sugar.

(e) We have not been able to demonstrate a capsule in any of our strains; Knott finds a capsule in 2 out of 6 strains.

(f) All his strains grow well at 22°C.; we did not get any growth at 22° to 23°C.

Classification of the bacillus.—So that these 13 strains can be put together in the genus *Eberthella* under the tribe *Bacteriæ* in the family *Bacteriaceæ*. In its specific characters the organism is nearest to *Eberthella phaffi*, the causative organism of fowl typhoid, being non-motile, a non-lactose and non-dulcitate fermenter, forming acid in glucose, in saccharose and usually in mannite, and producing no change in litmus milk.

Its pleomorphic character makes it resemble superficially *Klebsiella pneumoniae* Friedländer from which it differs in the following details :

(1) No capsule is seen.

(2) Growth not so abundant as in case of *Klebsiella pneumoniae*.

(3) No gas is produced in any of the sugars fermented.

(4) Non-pathogenic to mice, rats and rabbits. *Klebsiella pneumoniae* is highly pathogenic to mice; rabbits are less susceptible.

TABLE IV.
Details of cases having *Gram-negative-bacilli in sputum.*

Serial number	Case number	Age and sex	Duration of illness	Age at onset	Effect of season or weather	Pre-asthmatic state	Blood count		Sputum eosinophiles	Treatment	Result

Relieved

= Completely relieved of symptoms.

Much improved

= Intervals between attacks considerably increased, and the duration and acuteness of attacks lessened.

Improved

= Definite improvement but not very marked.

Not improved

= No improvement at all.

Before completing the description of the bacillus it may be worth while to refer to the few experiments carried out with a view to observing if the injection of the organism has any effect on the blood or tissue eosinophilia.

1. Broth culture of the organism injected subcutaneously in mice. Result—no local eosinophilia.

2. Broth culture of the organism injected into the pleural cavity of mice. Result—no local eosinophilia.

3. Filtrate from the broth culture injected intradermally in one patient (repeated injections). Result—doubtful increase in the blood eosinophilia, i.e., variations from none to 280 per c.mm.

A table detailing of the cases with the Gram-negative-bacilli in the sputum is given.

POINTS FROM THE TABLE.

(1) Sputum eosinophilia. Out of 27 only 8 show eosinophiles in the sputum (out of the series of 150 cases 36 show eosinophilia of the sputum, and of the 79 cases of bronchial asthma not associated with Gram-negative-bacillus infection only 16 show eosinophiles in the sputum), so that cases with Gram-negative-bacillus infection have a higher incidence of sputum eosinophilia than other cases, but we have not found the incidence as high as in Knott's cases; he finds seven-eighths of his cases showing sputum eosinophilia.

(2) High blood eosinophilia. This is not referred to by Knott, but in a personal communication he says 'all the patients infected with bacillary strains have shown eosinophilia (blood and sputum) or other manifestations of allergy'. This high blood eosinophilia has been shown by us to be of diagnostic importance.

(3) Out of 27 cases 13 gave a history of inheritance (in the total series of 150 cases only 40 gave a hereditary history, and out of 79 bronchial cases not due to these Gram-negative-bacilli, only 15 gave a history of inheritance).

(4) Age of onset. In 22 cases the age incidence varies from 11 to 30 years, and in 5 the age of onset was above 30 years and of these 4 started within 36 years; there was only one patient who commenced his asthmatic attack at 45 years. (In 38 of the 79 bronchial cases without infection with the Gram-negative-bacillus the age of onset was above 30.)

(5) Effect of season. Out of 27 only 10 cases gave a history of seasonal variation and of these 7 were worse during the winter and rains or got the attacks only at this season, one was worse in summer, and two worse during extremes of temperature. (Of the 79 bronchial cases not infected with the bacillus 35 shows seasonal variation and, of these 35, 29 were worse during the winter and rains, or got attacks only at those seasons.)

(6) Pre-asthmatic state. Of the 27 cases 18 or two-thirds gave histories of a previous illness,

i.e., 8 pneumonia, 7 chronic bronchitis, 2 nose and throat troubles and 1 dysentery. (Of the 79 bronchial cases without infection with this bacillus 52 gave a history of previous illness, i.e., 16 pneumonia, 30 chronic bronchitis, 4 nose and throat, 1 dysentery and 1 urticaria. Of the 22 gut allergic cases as many as 8 have a history of previous dysentery—the importance of the fact will be discussed in another paper.) A history of a previous pneumonia attack is more common in these cases than in the bronchial cases not infected with these bacilli.

(7) Result of treatment. Of the 27 cases 22 were treated (5 did not come for treatment) and the results of treatment are only available in 21 cases. Of these 21, 13 were completely relieved of their symptoms (there was 1 relapse in these 13), 3 were much improved, the intervals between the attacks having increased and the duration of the attacks lessened, while 4 were only slightly improved and 1 not improved at all. (In bronchial cases without the Gram-negative-bacillus infection, of the 49 cases treated 28 were relieved, 12 much improved, 8 improved, and 1 not improved.)

The following additional points which are not included in the table are worth mentioning.

(1) The co-existence of other allergic manifestations. In our total series of 150 cases of asthma there was only one case suffering from allergic dermatitis, and it was one of these Gram-negative-bacillus cases.

(2) History of previous allergy. Out of this series only 2 gave a history of having suffered from urticaria, and two suffered from sneezing and running of the nose before getting asthma. (In the total series of 150 cases 11 had suffered from urticaria previously.)

(3) Dermal tests were performed with extracts of the different hairs, feathers and foods in general use, when indicated in the history; grass pollens were included. Of the 25 cases tested only 3 gave positive results, one with cattle-hair, one with several foods and one with Timothy-grass pollens and milk. The positive tests did not prove to be of any value from the treatment point of view. (In the 67 bronchial cases without the Gram-negative-bacillus infection in whom dermal tests were done 57 were negative, 3 doubtful and only 7 positive.)

(4) Von Pirquet tests. Of the 16 cases where this test was done only 7 were positive. (In the bronchial cases without this bacillus infection 35 out of 60 were positive.)

(5) Evidences of pulmonary tuberculosis. There were only 3 cases showing any evidence of this disease and all these were old healed lesions detected in the skiagrams. (In the 79 bronchial cases there were 15 tuberculous cases of which one was an early case, 4 with well advanced lesions, and 10 with old healed lesions.)

(6) In none of the 27 cases did a change of place or food have any effect on the attacks.

Discussion.—Relation of the bacillus to asthma.

As already mentioned Oriel (1932) considers that the local production of histamine in the bronchi in addition to causing a contraction of the plain muscle surrounding the bronchi would also tend to increase the permeability of the epithelium lining the bronchioles and facilitate the entrance of foreign proteins and possibly bacteria.

Knott in a personal communication says that he thinks that the weight of evidence is that the organisms cannot themselves provoke an attack of asthma in a perfectly normal person, but only in those whose bronchioles are already irritable and on the verge of contraction; in allergies these infections are therefore particularly potent in precipitating clinical attacks or maintaining chronic asthma.

Our cases do not fall under the allergic group as is evident from the results of dermal tests and from the absence of any other associated allergy or history of previous allergy. We have not succeeded in demonstrating any histamine-like effect in cultures of the organisms isolated by us. The only thing we can say at present is that in our study of 150 cases of asthma we have come across 27 cases which constitute a clinical group amongst the bronchial cases characterised by high blood eosinophilia and presence of pleomorphic Gram-negative-bacilli in smears and cultures of sputum.

SUMMARY.

1. Morphological and cultural characters of the Gram-negative-bacilli isolated from the sputa of asthmatics are described. The classification and significance of these bacilli are discussed.

2. A table of the cases showing the Gram-negative-bacillus in their sputa is given and the following conclusions made.

(a) All the cases show a high blood eosinophilia and less than one-third show a sputum eosinophilia.

(b) About half the cases gave a history of heredity.

(c) Age of onset in more than three-quarters of the cases varies from 11 to 30 years.

(d) The response to treatment by vaccine made from these organisms is the same as in bronchial cases due to other bacteria.

(e) In only one case was there any other co-existing allergic manifestation, but two gave a history of having suffered from urticaria and another two patients suffered from sneezing and running from the nose before getting the asthma.

(f) The dermal tests are of no value in the diagnosis of these cases.

BRIEF NOTE ON THE RESULTS OBTAINED WITH ANTI-GAMETOCYTE TREATMENT ONLY, WITHOUT ANTI-LARVAL MEASURES

By W. W. CLEMESHA,

LIEUTENANT-COLONEL, I.M.S. (retd.)

Malaria Control Scheme, 'Daytona', Kandy, Ceylon

THE work of Barber, Komp, and Newman (1929) showed that very small doses of plasmoquine (0.01 gramme twice a week) were sufficient to prevent gametocytes infecting anophelids. The writer of this note has made a large number of practical trials of this method on estates, endeavouring to keep the coolie population free from malaria by the use of the anti-gametocyte action of plasmoquine *only*. For a variety of reasons, which need not be described here, many of the early experiments failed to produce conclusive results. This year, however, three very carefully controlled experiments were carried out during the malaria season, the results of which it is desired to describe briefly. Before doing this, it should be stated that the application of the prophylactic dosing *only* to estates can be carried out in two separate ways, (1) dosing two or three times a week of all members of the community for a period of 8 to 12 weeks during the period of active spread of malaria, and (2) in excessively bad areas where anti-larval measures happen to be impossible, dosing the whole community with quino-plasmoquine, two doses a week, year in and year out. It is intended in this brief note to give some results of both kinds of work.

As regards the first class, the following estates were treated to two (in a few cases three) doses a week of quino-plasmoquine for a period of about ten weeks:—Delwita, Daisy Valley and the lower divisions of Pitakande.

(Continued from previous column)

As regards the second class (continuous treatment) these are the two divisions of Mahabirattenne and the Victoria division of Pallakelley.

We will first say something concerning the first group. All of these estates are located in an area of very high endemicity, viz, the Kurunagalla District; the village spleen rate is between 80 per cent. and 90 per cent. at all times of the year; that on estates is considerably lower. The district is situated at the foot of the hills and many streams arising in the hills pass through it; these rivers are the main breeding places of *Anopheles culicifacies*; it is this species which does all the damage.

Delwita.—It is not possible to give in detail the facts regarding the outbreak of malaria on this estate; they can be summarized as follows:—The population of a little under 400 lives in lines on both sides of the Dedru-Oya, which under suitable conditions pours out an enormous number of *Anopheles culicifacies*. This year the conditions were highly favourable for about 8 to 10 weeks during July and

every case that sickened with fever was taken, and a remarkable condition of affairs was discovered, namely, (1) more than half the blood slides showed no parasites at all, although there can be little doubt that the infection was true malaria (anybody who had fever is included in the figures, whether parasites were found or not); (2) two days of 30 grains of quinine cured the patient, in spite of the fact that most of the cases were malignant tertian (*P. falciparum*); there was only one serious case out of the 76, all the others resembling a mild infection of benign tertian, and the number of days absence from work was very small. The outbreak demonstrates a fact which is well known to all malariologists, namely, that when there are a large number of vectors (in this case *Anopheles culicifacies*) extraordinarily few gametocyte carriers are sufficient to cause an outbreak.

Daisy Valley.—The estate of Daisy Valley is situated a few miles away, in the same district. There are rivers on both borders, from which *A. culicifacies* larvæ were obtained in large

August; larvæ were plentiful during this period and were caught regularly by our assistant; malaria itself was very prevalent in the neighbouring villages. The dosing was very carefully done by the dispenser, who is a conscientious and hard-working man; the scattered nature of the lines rendered the work of dosing the labour force rather difficult; a few babies in arms were omitted, the parents keeping the children hidden away. The results of the campaign were in a measure satisfactory, but were only partially successful; 20 per cent. of the total labour force sickened with malaria. Half way through the epidemic, we discovered two or three babies under 18 months of age had not received their regular dose, and it is highly probable that the local *anopheles* obtained their malarial parasites from these. A blood slide of

numbers. The population on the estate is 105 souls. Two doses a week were administered by the superintendent himself, because the estate being small no separate dispenser is kept. There was not a single case of malaria during the whole period, and practically no sickness of any kind whatever. The neighbouring villages suffered severely. Half way through the dangerous time, the blood of 34 children was examined. They were free from parasites, with the exception of five; there were only two dangerous individuals, both showed quartan gametocytes, amongst this group. The measures were a success and kept the labour force entirely free from malaria during a moderately severe outbreak among the civil population.

Pitakande.—The estate of Pitakande is in the same district and only a few miles away,

but the results obtained on this estate are nothing like as convincing as on the previous two, for two reasons, namely, (1) several years ago, at my recommendation, all the lines near the river were pulled down and rebuilt on a better situation, and (2) most of the lines are on high ground at the foot of the hills, not on the plains themselves. Prophylactic dosing was given during the bad period of October and November to all, except the top division. No cases of malaria resulted, but many estates and villages in the neighbourhood suffered severely.

Dealing now with the second class of work, it is necessary to say that the two divisions of Mahabiratenne and Victoria division are situated on the angle between the two large rivers, the Hulu Ganga and Mahaweli Ganga. The distances of the three divisions from the river are as follows :—

The central division of Mahabiratenne is about two and a half miles from the river, spleen rate in 1927 (before measures were adopted) 12 per cent. The Henegahawela division of Mahabiratenne is about three-quarters of a mile distant, spleen rate in 1927, 25 per cent. Victoria division is three to four hundred yards distant, spleen rate in 1927, 100 per cent.

There are practically no minor breeding places on the three divisions. All small streams and puddles dry up within ten days of the cessation of the rains. It is quite impossible to do anything in the shape of anti-larval measures to the Hulu Ganga and Mahaweli Ganga, consequently, the only measure which will give the slightest hope of success is continual dosing. Regular dosing, twice a week, year in and year out, was carried on on the two divisions of Mahabiratenne from June of 1930, and on the Victoria division from January of 1931. The results since then are given as follows :—

	Popula- tion	TOTAL CASES FOR THE YEAR		
		1930	1931 *	1932 *
Central division, Mahabiratenne.	325	66	20	5
Henegahawela division of Mahabiratenne.	300	62	24	6
Victoria division of Pallakelley.	250	80	29	10

* Blood films taken in all cases.

During the years 1930 and 1931 there have been two violent epidemics in the civil population; there was very little ill-health in 1932. The labour in Mahabiratenne and Victoria entirely escaped these outbreaks, as the figures above and the chart show.

In a brief statement like this, it is impossible to convey any idea of the change that has taken place within three years. The children are now

fat and healthy and practically free from parasites; the out-turn to work amongst the adults now is well over 95 per cent., and the saving to the company is very great. In 1928, conditions were lamentable.

During the spring of 1932 our investigations showed that *Anopheles culicifacies* was decidedly rare, so that from December 1931 to July 1932, no prophylactic dosing was considered necessary. This course was adopted largely in the interest of economy, as the companies owning the estates were very anxious to save every penny on account of the condition of the market. No ill-results whatever have occurred from this cessation of the dosing up to date, but it must be stated that 1932 was a healthy year in this district; the malaria figures in the civil population were low.

The examination of the blood of the children on Victoria has shown that, since the use of plasmoquine, the only parasite that survives is 'quartan'. At the last blood slide examination, November 1932, 10 per cent. of the children had quartan parasites in their blood; Atcbrin is being tried to remove these.

Conclusions

In spite of the somewhat small number of these trials, the results show that it is possible to control entirely the spread of malaria by careful anti-gametocyte work. This appears to be quite easy in cases in which the prophylactic doses are given over long periods, as a regular procedure. When given over a short period of great danger, they are equally successful, provided certain conditions are rigidly adhered to.

2. If a high degree of success is wished for, a thorough comb-out of gametocyte carriers in the labour force must be undertaken. This usually means examining the blood of all children and adults in bad health, babies in arms to receive particular attention, because of the likelihood of these missing the bi-weekly dose.

3. The search for and cure of gametocyte carriers should always be undertaken at least a month ahead of the onset of the dangerous period.

4. In a community receiving two doses of quino-plasmoquine a week, those who sicken with fever show extraordinarily few malaria parasites (trophozoites or schizonts) in the peripheral circulation. Malignant tertian and benign tertian gametocytes will never be found if the dose is taken regularly. Quartan parasites and gametocytes are much more frequently met with and are much less acted on by the plasmoquine, than the other two.

5. Two doses of quino-plasmoquine a week, causes the attack, even of malignant tertian, to be mild in character. The duration of the fever is usually two to four days, instead of eight to twelve days, and profound disturbance in health is only observed in very susceptible newcomers to the district.

6. The only objection to the regular treatment of a whole labour force is the trouble and expense involved. The cost for a whole year is much less than that occasioned by a severe outbreak of malaria.

The writer apologises for the paucity of the evidence brought forward in support of the above statements. Careful graphs are kept in the office of the Malaria Control Scheme, going back for a large number of years. They show the sickness rate in the civil population as obtained from the local hospitals, side by side with that of our estates. They are of very great interest and importance, but they are too large for suitable reproduction in a medical journal. If any of the readers are interested in a more detailed account of these occurrences, the writer is in a position to send them a copy of the records in our office, which gives all the evidence, and contains copies of the graphs. Any who would care to have these, will be supplied if application is made to Lieut.-Col. W. W. Clemesha, I.M.S. (retd.), Malaria Control Scheme, 'Daytona', Kandy (Ceylon).

CERTAIN INJURIES OF THE WRIST THAT ARE FREQUENTLY OVERLOOKED

By P. C. DUTTA, M.B., F.R.C.S. (E.), D.G.O.

CAPTAIN, I.M.S.

Surgical Specialist, Kohat District, Kohat

SOME of the injuries of the wrist and foot which appear trivial often pass undiagnosed. These injuries are as common in the civilian as in soldier, but the civilian, thinking the lesion to be of very minor nature, hardly ever consults the doctor. Even when he does so, the average general practitioner, not having the benefit of *x-ray* at his disposal, is liable to miss the exact pathological lesion. Whereas every case of injury in the army, however trivial it may be, is seen by a medical officer who has an *x-ray* apparatus at his disposal to confirm his diagnosis. The following injuries are discussed in this paper, some of these are common, others rare.

I. Sprain of the carpal scaphoid and semilunar.

II. Fracture of the carpal scaphoid.

III. Fracture of semilunar.

Of these, fracture of the scaphoid is very common and has been described in detail. Only a passing mention has been made of the others. Dislocation of the semilunar has not been included, as the condition is more or less evident on clinical examination.

Before describing the injuries of the scaphoid and semilunar, let us very briefly recapitulate the anatomy and physiology of these two

bones. The scaphoid is most liable to be injured on account of its shape and position. Its shape is like that of a rod the shaft of which is first curved vertically (body) and then its lower end bent perpendicularly (apophysis). Consequently there are two curves, one vertical to fit on to the head of the os magnum and the other antero-posterior formed by the junction of the apophysis and body.

The semilunar is crescentic in shape. The anterior ligament or ligamentum arcuatum is the only strong ligamentous attachment of this bone. Its concave surface fits badly with the head of the os magnum and the beaks, anterior and posterior, are not long enough, hence the bone is easily displaced.

The bones of the carpus are very badly nourished, and the vessels are supported in the ligaments. So when the latter are ruptured, there is always trouble with the nutrition of the bone.

Radiography.—Two plates must always be taken for a correct diagnosis. One antero-posterior and another lateral. For the first the posterior surface of the forearm is placed against the plate and the rays are directed to the centre of the radio-carpal space. For the second, which is more difficult to take, the radius is placed against the plate with the hand in the same plane as the forearm. This can be done by turning the arm and making the patient bend the body, i.e., the arm being in a position slightly higher than the body. In the profile skiagram the scaphoid looks like a bean. The outline of the semilunar is well marked in the lateral picture and its characteristic form is evident.

I. SPRAIN OF THE SCAPHO-LUNARY JOINT

Destot (1925) classified sprains of this joint into five clinical varieties.

1. Mild and simple; in this only clinical symptoms are present.

2. A more serious type associated with subluxation of the semilunar.

3. Where the subluxation has reduced itself, but the ligaments are torn and small fragments of the bone may later form osteophytes.

4. Old sprains with osseous degeneration.

5. Spring wrist or recurrent subluxation of the scaphoid and semilunar.

In this article only the recent injuries are discussed, so we shall confine ourselves to the first and second types.

Clinical features.—The injury is usually caused by falling on the hyper-extended hand. There is pain and swelling in the anatomical snuff-box. Ecchymosis may be present in the thenar eminence. There is no swelling at the back of the hand and crepitus is absent. The most tender point is just below the styloid process of the radius and the whole of the internal part of the wrist is free. Pain is experienced if the space between the scaphoid and semilunar is pressed between the fingers. If pressure is applied between the scaphoid and trapezium

while the thumb is being moved, acute pain will be felt. The height of the wrist is decreased only in persistent dislocation of the semilunar. Passive movements are invariably limited, particularly bending the hand to the radial side. In subluxation, supination and pronation are also limited.

Radiography.—In the antero-posterior skiagram the scaphoid appears globular and shortened. Its upper extremity overhangs the dorsal surface of the os magnum and throws a marked shadow on the head of the latter. The space between the scaphoid and semilunar is either increased or diminished and the scaphoid appears continuous with the semilunar on which it lies. The side view is more important. The semilunar and scaphoid do not make a continuous carpal condyle which appears bigeminate as the curves of the two bones do not fit into each other. In order to make the lesion apparent a schematic radiogram is given instead of a true x-ray photograph.

Active and passive movements are started after a week.

II. FRACTURE OF SCAPHOID.

Frequency.—It is a fairly common injury. Patterson Brown (1928) reported that 46 cases were treated in the Edinburgh Royal Infirmary in the course of two years. Ross and Wibert, quoted by Destot, state that it represents 9 per cent of all fractures. I saw six cases last year and seven in the last eight months of this year. Forty-three cases of fracture have been treated in the Kohat Military Hospital in the last eight months including seven fractures of scaphoid; in other words it formed about 16 per cent of all fractures treated in the hospital. For this purpose statistics of big civil hospitals do not show the true frequency of the injury, because they deal more with cases of major fractures, and patients with minor injuries seldom report there. Quite a lot depends, of

Fig. 1.

Fig. 2.

Fig. 3.

Fig. 4.

The displacement is indicated by the x.

The upper pictures are antero-posterior and lower lateral views.

Figs. 1 and 3 are normal and Figs. 2 and 4 with subluxated semilunar.

Treatment.—The wrist should be immobilised in a small cardboard splint, leaving the fingers free, for one week. The hand is kept slightly inclined to the ulnar side. To reduce subluxation the bone is pressed between the thumb and fingers and the hand is simultaneously extended.

course, on the number of cases that can be x-rayed. The point I want to stress is that it is a very common injury and should always be looked for, because with early diagnosis and treatment complete cure can be assured in 90 per cent, whereas some functional impairment

(disability varying from 10 per cent to 40 per cent) is the rule in late cases.

Mechanism of fracture.—The fracture is produced by falls on the hyper-extended hand. In falls of this nature the most direct line of transmission of the body weight is through the scaphoid. It has already been pointed out that this bone has two bent axes and therefore is very liable to break. After impaction it undergoes a bell-like movement (Destot), which brings the upper extremity of the bone posteriorly. At this moment one of the following injuries is liable to occur, according to the exact way in which the body weight is resisted.

trapezium and trapezoid. The force crushes the scaphoid along its long axis producing a transverse impacted fracture of the bone across its middle.

4. If the hand is violently adducted, the external lateral ligament may be torn off the tuberosity of the scaphoid.

Symptoms and diagnosis.—Very few special symptoms are produced by the fracture, and therefore it is so liable to be overlooked. Swelling, pain and tenderness in the anatomical snuff-box are the main symptoms. These are also present in sprains of the wrist joint and fracture of the styloid process of the radius. It should be remembered that fracture of the scaphoid is commoner than sprain of the wrist joint (apart from the sprains of the tendons about the joint). Crepitus can very seldom be elicited. Symptoms of compression of nerve

Skiagram 1.—Incomplete fracture of scaphoid without any displacement.

Skiagram 2.—Complete fracture without any displacement

1. If the limb is not quite perpendicular to the ground (the scaphoid is firmly fixed into the glenoid cavity of radius) the body weight is transmitted through the radius, which is at a mechanical disadvantage and it breaks.

2. If the hand is inclined on the radial side, the scaphoid lies between the radius and os magnum. In this position the head of the os magnum is driven like a wedge into the concavity of the scaphoid and the latter will break across its middle.

3. If the hand is inclined to the ulnar side, the scaphoid comes further out of the wrist joint and lies with the long axis almost vertical between the styloid process of the radius,

trunks or vessels may be produced by the displaced fragment, but this is very rare.

'Tapping pain'.—It was described by Murphy. The hand is held in radial flexion with the fingers flexed. The distal ends of the metacarpal bones are gently struck with a percussion hammer. On striking the third metacarpal, the os magnum is driven against the scaphoid and in case of a fracture even a slight tap causes pain.

Tapping pain in fracture of the scaphoid is most marked when the hand is in radial deviation. In fracture of the semilunar it is most marked when the hand is in ulnar

deviation. No pain is produced in dislocation of the semilunar.

Prognosis.—It is the universal experience that the end results of fracture of the scaphoid which has been overlooked, tend to be a good deal worse than those which are recognised and treated immediately. Prognosis for recent cases is good.

According to Bankert (1932) the treatment advocated by Bohler appears to have improved the end results even in late cases to a great extent.

Treatment.—To reduce the displacement, the hand is flexed and deviated to the ulnar side, pressure is applied at the same time in the anatomical snuff-box, and the broken pieces are

impaired, it was the usual custom to excise the fractured fragments. But recently Bohler has demonstrated that if these cases are kept immobilised in dorsiflexion in a plaster splint for *four to six months*, bony union will occur not only in recent cases but even in late cases. The splint is applied on the dorsal aspect of the hand and forearm, extending from the base of the fingers to the elbow joint with the wrist in slight dorsiflexion and ulnar adduction; this treatment should be carried out in all late cases.

If bony union does not take place even after six months the fragments may be excised, but the results are not very satisfactory.

III. FRACTURE OF SEMILUNAR

It is a rare injury, but recent literature shows that it is not so rare as it was formerly believed

Skiagram 3.—Complete fracture with slight displacement of the upper fragment.

moulded on to the head of the os magnum. A plaster splint is applied and the hand is kept in dorsiflexion for two weeks. The splint is then removed and massage and movements are commenced.

Fractures of the tuberosity, being extra-articular, heal readily after immobilisation for two weeks.

Intra-articular transverse fractures do not heal so readily and may produce a certain amount of functional impairment. Owing to this, specially in those cases which are seen late and in which free movements of the wrist are

Skiagram 4.—Complete fracture with appreciable displacement of the upper fragment and subluxation of the semilunar.

to be. Fracture of the semilunar does not produce any pathognomonic clinical sign and therefore it is very difficult to diagnose. Moreover as it is often associated with small intra-articular fracture of the radius, these often pass unnoticed. The only findings on clinical examination are very slight limitation of the movements of the wrist, slight swelling in the anatomical snuff-box, and a little antero-posterior thickening when the bone is palpated between the fingers.

Tapping pain is most marked on tapping the head of the third metacarpal when the hand is in ulnar flexion.

DIFFERENTIATION FROM DISLOCATION OF THE SEMILUNAR

(a) In dislocation there is appreciable thickening of the wrist due to, (i) prominence on the dorsum formed by the head of the os magnum displaced backwards, and (ii) swelling in front beneath the flexor tendons caused by the dislocated semilunar. In fracture there is swelling of the wrist, but not so much thickening.

(b) Shortening of the carpus as evidenced by the position of the head of the third metacarpal. The head is at the same level or proximal to the heads of the second and fourth metacarpals in dislocation. In fracture the head of the third metacarpal is distal to the others as in a normal case.

(c) In dislocation slight palmar flexion is possible, but dorsal flexion is resisted, whereas in fracture slight dorsal flexion is usually permitted.

(d) Dislocation generally produces symptoms due to pressure on the nerves or vessels. This is hardly ever present in fracture.

(e) Tapping pain is absent in dislocation.

(f) X-ray. In a lateral skiagram in dislocation the concavity of the semilunar does not fit like a cup on the head of the os magnum.

Prognosis.—With early diagnosis and treatment, it is good, but Kienböck's disease is liable to supervene later on.

Treatment.—Germans advocate removal of the bone in all cases. French and British surgeons prefer more conservative methods and advise immediate mobilisation massage and movement in addition to alternate hot and cold douches. If in spite of this the patient does not improve, the bone should be removed. This is further recommended on the ground that Kienböck's disease is liable to supervene.

For removal of the bone British surgeons use a dorsal incision, about 2 inches long, over the lower end of radius and the carpus. Destot prefers a horse-shoe-shaped incision over the middle fold of the flexure of the wrist, between the tendons of palmaris longus and palmaris brevis. He thinks that operation by the posterior route is much more difficult and mutilating. The operation is much easier with a tourniquet round the arm.

HYDATID DISEASE IN SOUTH INDIA

By V. MAHADEVAN, M.R.C.P., F.R.C.S.E.
MAJOR, I.M.S.

*Superintendent, Royapuram Medical School, and
Surgeon, Government Royapuram Hospital, Madras
and*

T. BHASKARA MENON, M.D., M.R.C.P.
*Pathologist, Government Royapuram Hospital and
Medical School, Madras*

Few cases of hydatid disease have been reported in India. The general impression is that the disease is rare. It is only occasionally that cases appear in the hospitals in large towns, and even these very often are not clearly brought out in hospital reports. The provincial annual reports in India show no separate heading for hydatid disease, and in hospital reports they are included under tumours. It is therefore difficult to arrive at an estimate of the real prevalence of the disease in India. The dog, the natural host of the *Ecchinococcus granulosus*, though present in numbers, is rarely the household pet and companion of man as in

Illustration showing the large cyst arising from the lower pole of the left kidney. A portion of the hydatid membrane can be seen projecting from a tear in the upper part of the cyst.

Europe and Australia. Amongst both Mohammedans and Hindus, owing to religious scruples, dogs are rarely allowed in-doors. This might be a possible explanation of the rarity of the disease here, but it is equally possible that, as the senior writer holds, the condition is frequently overlooked. This paper therefore is intended to emphasise the not uncommon occurrence of this condition in south India where the senior writer has met with seven cases in the course of the last eight years.

The only possible means of estimating the prevalence of this condition in south India, since hospital reports are so meagre in this respect, is by an analysis of the cases of proved hydatid disease that are reported as such by the pathological department of the Madras Medical College, which serves as a central laboratory to which most specimens from the district and mofussil hospitals are sent up for pathological examination. We have been able to analyse the number of cases of proved hydatid disease through the courtesy of Dr. A. Goyle, professor of pathology of the Madras Medical College, from the records of the last 10 years. No cases were reported in 1923, 1926, 1927 and 1929; the incidence in the other six years is as follows:—

Year	Number of cases	Site of cyst	District
1924	one	liver	Madras
1925	one	abdomen	Madras
1928	one	liver	Madras
1930	two	abdomen	Madras
		liver	Madras
1931	one	not known	Anantapur
1932	two	liver	Kurnool
		neck	Anantapur

It will be noticed that only eight cases have been reported for the whole of the presidency during the last ten years.

The cases reported below serve to show that the real incidence is more than is apparent from the above figures, if care is taken to look out for this condition. It is possible that many cases of obscure enlargement of the liver looked upon as abscess or gumma are really cases of hydatid disease. Some puzzling abdominal tumours may come under the same head. These cases also serve to show what varying clinical types are presented. Five of these cases occurred while the senior writer was out in the districts during a period of six years, and the other two were patients that came up to Madras and were admitted to the wards of the Government Royapuram Hospital for treatment.

Case 1. Cyst of the liver.—R., Hindu, aged 45 years, came up for treatment to the District Headquarters Hospital, Vellore, in 1923 for a cystic tumour of the liver. On operation it was found that the cyst extended down into the peritoneal cavity and had formed adhesions to the colon and small intestines. It was a unilocular hydatid. Adhesions rendered the removal of the tumour *en masse* impossible, so the cyst was opened, irrigated and touched with formalin; the patient recovered without any complications.

Case 2. Cyst of the breast simulating cystadenoma.—Mrs. K. P., a young married Hindu lady, aged 35, came up for treatment to the District Headquarters Hospital, Guntur, in July 1929 for a tumour of the breast of four months' duration. The tumour was of the size of an orange, cystic and slightly tender. No suspicion of hydatid disease was entertained, since cystadenoma of the breast with large cysts is quite a common condition. On operation, however, it was found to be a large hydatid with a well-developed thick ectocyst and a delicate endocyst, besides the fibro-fatty capsule outside the cyst. A number of daughter and grand-daughter cysts were found inside the primary cyst indicating an endogenous development.

Case 3. Cyst of the abdomen simulating ovarian cyst.—C., a young Hindu lady, aged 31, came to the Hospital for Women and Children, Vannarpet, Palamcottah, in August 1926, for a tumour of the abdomen of two years' duration. The patient was a multipara and had four children. There was a large cystic tumour in the abdominal cavity. On operation this was found to be a large hydatid arising from the omentum, adherent behind but freely movable in front. The cyst was multilocular having three septa and containing daughter and grand-daughter cysts. The cyst was marsupialized and the patient had an uneventful recovery.

Case 4. Cyst of the liver.—J. C., a young Indian Christian girl of 25 years, came to the same hospital at Vannarpet for cystic tumour of the liver, in March 1925. The cyst was of two years' duration and extended down into the abdominal cavity. On operation it was found to arise from the under surface of the liver and to extend down to Poupart's ligament, displacing the liver upwards and pressing on the diaphragm. There were numerous adhesions to the omentum and coils of the intestine. The liver substance was stretched out and atrophied. Small cysts indicating an exogenous development were found in the right lobe of the liver. The cyst itself was multilocular. The patient made an uneventful recovery after operation.

Case 5. Suppurating hydatid simulating subphrenic abscess.—In July 1927, in Madura, K. A., a young Chetty girl, aged 13, was seen by the senior writer in consultation, for a swelling in the region of the liver. There was a history of fever with rigors for one month, and the gradual formation of a swelling in the upper abdomen on the right side. The blood showed a leucocytosis. The clinical features were suggestive of subphrenic suppuration, and exploration and drainage were decided upon. The tumour was incised and pus, yellowish in colour with no fecal smell, was found. A large amount was evacuated, but the sinus persisted. Fifteen days after the operation, gentle pressure brought out two small daughter cysts. The incision was therefore enlarged, all the daughter cysts were removed, and the wall was touched with formalin. The wound healed without any further trouble.

Case 6. Multiple peritoneal cysts causing retention and extravasation of urine.—K., a Hindu, aged 46 years, was admitted to the Government Royapuram Hospital in September 1931 for extravasation and retention of urine. Rectal examination showed a lumpy growth in the sacral region which was irregular. Nothing could be made out through the anterior abdominal wall owing to rigidity. A sacral tumour causing pressure on the urethra was thought possible, but on exploration the whole pelvis was found filled with five or six cysts covered over by the omentum. These were removed *en masse*, and microscopical examination showed typical hydatid structures with hooklets.

Case 7. Hydatid cyst of the kidney.—Mrs. M. B., a Mohammedan lady, was admitted to the Government Royapuram Hospital in January 1932. She had come from Guntur district for treatment for a swelling in the left side of the abdomen of five years' duration. It had started as a small tender swelling in the left lumbosacral region and had gradually increased in size for the last five years, till it extended from very near the left costal margin to the iliac crest. There had been a low type of fever for some months. The patient was a multipara, had three children, two boys and one girl, and her menstrual history was regular. Her general health was good. On examination the tumour was found to be tense and cystic, and to occupy the whole of the left side of the abdomen with a small projection to the right side about one inch above the umbilicus. There was slight movement with respiration. The skin was freely movable and the tumour itself was slightly movable from side to side. The surface was irregular and appeared divided into three lobes. The differential leucocyte count showed marked lymphocytosis. Eosinophiles were only 3.5 per cent. There was no

albumin in the urine, and urinary symptoms were absent. On operation the tumour was found to be a large cyst arising from the lower pole of the left kidney. The descending colon was adherent to the left side. The cyst had pressed on the ureter below and caused a slight hydronephrosis. The cyst and the left kidney were removed and on examination all the three layers of the hydatid were made out. The outer was the fibro-fatty capsule of the kidney. The contents consisted of clear watery fluid. Microscopical examination of a scraping from the endocyst showed scolices and hooklets.

Comment.—The occurrence of hydatid cysts in the breast in case 2 is certainly unusual, and is a factor to be borne in mind in the diagnosis of cystic tumours of the breast. The development of multilocular cysts in cases 3 and 4 is not in agreement with the idea of a restricted geographical distribution; this is claimed to be different from that of ordinary unilocular cysts. On the other hand, these cases occurring in India suggest that the multilocular cyst is a mere variation in the development of the cyst, which might be partly due to a defective formation of the ectocyst allowing an extra-capsular budding. In case 6 the multiple peritoneal implantation cysts apparently arose from a primary cyst in the recto-vesical pouch. Retention of urine due to pressure of a cyst on the prostatic urethra has not been hitherto reported, and might puzzle the clinician if this condition is not borne in mind. The cyst of the kidney in case 7 offered great diagnostic difficulties since abdominal tumours in this situation show many variations from the common clinical types.

It is noteworthy that an examination of the blood in cases 6 and 7 did not reveal an eosinophilia. The eosinophilia of hydatid disease, while it may be well marked at the commencement, may gradually subside, probably because the mother membranes undergo degenerative changes. This fact should be borne in mind and the absence of eosinophilia should not be taken as a negative indication, especially in old cases.

In view of the recent work on Casoni's intradermal reaction for hydatid disease and the positive results in 90 per cent. of cases reported by Dew and Kellaway, it is worth while that this simple cuti-reaction be made use of in India in all obscure tumours and cysts that occur in and about the abdomen.

THE ZONDEK-ASCHHEIM TEST FOR PREGNANCY AS STUDIED IN 200 CASES*

By K. B. MUKERJEE, B.Sc., M.B., Ch.B. (Edin.),
L.M. (Dublin)

Clinical Laboratory, Mackinnon, Mackenzie & Co.,
Calcutta

THE investigations of Zondek, Aschheim, and Popanicolau on the functions of certain of the glands of internal secretion are now so well known that they are even a subject of undergraduate physiology. These studies have inci-

dentally led on to a biological test of pregnancy, known as the Zondek-Aschheim (1928) reaction; it is with this test that this paper is concerned.

After I had carried out the original test on twenty cases I began to doubt if the test could have a wide application since the clinician has to wait for the report for five days—rather a long time when he is faced with a case of, say, tubal pregnancy.

The use of immature white mice has some practical disadvantages; the disadvantages are: (a) sex-differentiation—recognition of the sex of immature mice is by no means easy; (b) the animals have to be bred for quite a long time to obtain immature females of nearly the same age ready for the test; (c) these small animals do not tolerate injections of large quantities of fluids, and thus the speed of the test—a matter of importance in most cases in which we want to do the test—is sacrificed by the necessity for continuing the injections for 3 or 4 days.

For this and other reasons Reinhart and Scott (1931) and other workers have used the rabbit for pregnancy tests. It is not necessary to use immature female rabbits provided they are not pregnant, but for the sake of uniformity of results and in order to produce a maximal reaction it is better to use immature animals of nearly the same age, say, 2½ months old.

A catheter specimen of urine need not be used. It will be better however to use such specimens whenever possible. It is moreover desirable to know the drugs—such as alkaloids and the heavy metals—the patient might have been taking, and to test all specimens for albumin and micro-organisms. Sometimes I injected contaminated urines without any untoward effects, but more often the animals developed peritonitis within 12 hours. In cases of bacilluria I have found the procedure recommended by Stewart (1931) most helpful. This consists in shaking the urine with a little ether and allowing the ether to evaporate from the urine in the incubator. Then the sample is for all practical purposes sterile.

The intraperitoneal has certain advantages over the intravenous route, because large quantities of fluids are more easily introduced and because rabbits are very liable to die soon after intravenous injection of urine containing albumin—a substance we do not infrequently find in the urine of pregnant women. Some workers have advocated the intravenous injection of 5 c.cm. of urine on two consecutive days, but I gave one injection of 10 to 15 c.cm. intraperitoneally, in order to save time.

Finally, for suspected cases of chorionic epithelioma I used concentrated urine. As the anterior-pituitary hormone is thermolabile at 60°C. the best procedure is to evaporate the urine *in vacuo* at 45°C. With a good vacuum pressure 100 c.cm. of urine can be reduced to 10 c.cm. at this temperature in about two hours.

* Rearranged by the Editor.

It is not necessary to use concentrated urine for other cases—not even for anxious or nervous mothers in the earlier weeks of pregnancy—because the concentration of the anterior-pituitary hormone in the urine shoots up sharply to its maximum before the end of the first month of pregnancy, falling very slowly as months go on. Ordinarily my procedure is therefore to inject intraperitoneally two starved animals each with 10 to 15 c.cm. of the morning urine rendered sterile when required. (The urine can be kept for 48 hours in a refrigerator without any loss of its hormone content.) For about an hour the rabbits lie flat in the lateral position, but with absorption of the fluid from the serous membranes they recover.

The results.—The results of the test, as ascertained by the presence or absence of hæmorrhagic follicles, are obtained after 24 hours. One does not always find ovaries studded with such follicles; nor does it seem to me that the number of such follicles is related to the hormonal concentration of the urine injected. I have often noted rabbits of the same litter reacting differently to the same amount of urine of the same case. Even ovaries of the same animal reacted differently. With the same urine I have not however obtained a totally negative reaction in one animal and a definite positive reaction in another.

I have again cut serial sections, to search for atretic corpora lutea and microscopic hæmor-

under a magnifying lens is all that is necessary. In the first two months of pregnancy the effects of œstrin on the genital apparatus of the experimental animals are not marked, but later marked congestion and œdema are observed in the horns of the uterus, vagina, etc., along with the changes in the ovaries caused by the hormone of the anterior-pituitary body.

The cases

In this series of 200 cases, 40 were in the Eden Hospital, Calcutta. I must express my indebtedness to Lieut.-Colonel V. B. Green-Armytage, I.M.S., of that hospital, without whose guidance and constant encouragement I could not have investigated such a variety of cases as I have done.

In the interests of economy in space notes on these 200 cases have been omitted. The cases can be grouped in the following way.

Group I

Undoubted and uncomplicated pregnancy from 5th to 9th month.

Nos. 1—17 (Private cases).

Nos. 18—27 (Hospital cases).

Results.—Zondek-Aschheim reaction positive in all cases.

Group II

Undoubted pregnancy but complicated with psychosis, pre-eclampsia, accidental hæmorrhage, hydramnios, malaria, kala-azar, syphilis,

The ovaries in positive cases are larger than those of control animals or in negative cases, and show hæmorrhagic follicles. The microscopic sections show much infiltration of blood into the Graafian follicles and the corpora lutea; they also show atretic corpora lutea.

Figs. 1 and 2. Case 137.—A case of chorionic epithelioma. Result obtained with concentrated urine is negative macroscopically and microscopically. Serial sections do not reveal any blood follicles and atretic corpora lutea.

rhages, of ovaries—'normal' to the naked eye—of animals injected with urines of suspected cases; but I have not yet discovered either of these conditions in a 'normal' ovary. For diagnosis a thorough inspection of the ovaries

filaria, 'anæmia', influenza, true diabetes, pulmonary tuberculosis, etc.

Nos. 28—50 (Private and hospital cases).

Results.—Zondek-Aschheim reaction positive in all cases except No. 48.

No. 48: Multipara, aged 28; pregnant 8 months; psychosis—extremely melancholic with revulsion of feeling towards the husband.

Labour complicated, breech presentation; Zondek-Aschheim reaction negative.

Group III

Cases with presumptive signs or symptoms of pregnancy, amenorrhœa ranging from 15 days to 8 months.

Nos. 51—85 (private and hospital cases).

Results.—Zondek-Aschheim reaction positive except in Nos. 57 and 82. With these two exceptions they all showed definite signs of

correct except on one occasion, the details of which are as follows:—

No. 137. Here the patient was admitted on August 22nd, 1931, with a history of abortion which, she said, had taken place on August 18th, 1931. Curetted products showed hydatidiform mole. Admitted for the second time on September 11th, 1931, with metrorrhagia. Relieved and discharged. Third admission on September 27th for vaginal bleeding. Pathological diagnosis of curetted products—chorionic epithelioma. The Zondek-Aschheim reaction with concentrated urine was negative. Blood transfused on September 30th, and on October 2nd vaginal hysterectomy, bilateral salpingectomy and right ovariectomy were performed. On October 19th the patient was discharged as cured.

Fig. 3. Case 187.—A case of hydatidiform mole. Ovaries removed 24 hours after injection show both atretic corpora lutea and blood follicles.

Fig. 4. Case 51.—A case of toxic hyperemesis, which was treated in the beginning as 'bilious attacks'. Twenty-four hours after injection the ovaries show the usual signs.

pregnancy in the later months, and the dates of labour closely agreed to their calculations.

No. 57: Nullipara, aged 42. Married 30 years; sterile. Amenorrhœa for 3 months when first seen. Zondek-Aschheim reaction negative. No signs of pregnancy when seen after six months of amenorrhœa. (? Psychological, ? menopausal.)

No. 82: Multipara, aged 42. Five children. Asthma with heart failure and anasarca; anæmia; amenorrhœa of 7 months; no vaginal finding except a small cervical polypus. Zondek-Aschheim reaction negative. The patient did not show any signs of pregnancy later. Anæmia might have caused the amenorrhœa.

Group IV

Cases simulating anomalous pregnancy.

Nos. 86—200 (Private and hospital cases).

In this group are included cases of threatened abortion, ovarian cyst, fibroid, fibroid and pregnancy, tubal pregnancy, salpingo-ovariitis, pyosalpinx, cystic ovary, hydatidiform mole, endometrioma, hæmatometra, etc.

Surgical measures in the cases of this group showed that the Zondek-Aschheim reaction was

No. 107, who was another case of hydatidiform mole, could not be followed up. When she left the hospital the Zondek-Aschheim reaction was totally negative.

Discussion

So far I have not got a single false positive reaction though I have examined over 200 cases and serially sectioned many ovaries that show no hæmorrhagic follicles to the naked eye.

It will probably be fallacious to argue that since we get so small a percentage of error—about 2 per cent.—we can safely rely on such a test. Judgement has to be made entirely from the point of view of the clinician. There can, for instance, be no comparison between an anxious mother, otherwise well, wishing to know if her month's amenorrhœa is due to pregnancy and a case where tubal pregnancy is suspected. In quite a number of cases of the latter type laparotomy is clearly indicated. Nevertheless, positive results are always reliable and sometimes valuable. Take case no. 100 for instance; the patient had a large sub-peritoneal fibroid

plus amenorrhœa of over six months' duration. Diagnosis of pregnancy was difficult for various reasons, and could not be made for nearly six days, but the Zondek-Aschheim reaction was positive straight away.

I am much indebted to Dr. R. M. Bradley, M.D., Ch.M., Medical Superintendent, B. I. S. N. Co., Calcutta, for kindly allowing me to perform most of these experiments in the Mackinnon, Mackenzie & Co.'s Clinical Laboratory, Calcutta, and to publish this paper. I would also take this opportunity of thanking most sincerely Lieut.-Colonel V. B. Green-Armytage, F.R.C.P., L.M.S., Professor of Obstet-

rics and Gynæcology, Calcutta Medical College, Dr. S. J. G. Nairn, M.B., F.R.C.S., of the Presidency General Hospital, Calcutta, Dr. B. K. Das, D.Sc., Formerly Professor of Zoology, Calcutta University, and Mr. N. G. Chakrabarti, M.Sc., Demonstrator of Chemistry, Presidency College, Calcutta, for the help and guidance they gave me.

A Mirror of Hospital Practice

A RARE TYPE OF DERMAL LEISHMANIASIS

By E. MUIR, M.D., F.R.C.S. (Edin.)
and

S. N. CHATTERJEE, M.B., D.T.M. (Bengal)
Calcutta School of Tropical Medicine

Puzzling cases sometimes are sent to the leprosy outdoor clinic with a diagnosis of elephantiasis Græcorum which after a careful examination turn out to be cases other than leprosy. The undermentioned case is one of these.

The patient was diagnosed as a case of leprosy and referred by a doctor to the Albert Victor Hospital, Gobra, for admission. He was discharged after examination as he was not considered to be suffering from leprosy. Being disappointed he came back to the medical institute he attended on the first occasion. There

Fig. 1.—Front view of patient.

Fig. 2.—Photomicrograph of section taken from edge of annular lesion of arm. Note capillary surrounded by granulomatous cells, some (a) containing Leishman-Donovan bodies.

he was seen by another doctor who diagnosed the case as one of leprosy and referred him to the leprosy outdoor clinic of the Calcutta School of Tropical Medicine.

History and examination.—Seven years ago the patient suffered from an attack of 'fever' for about two months after which he noticed enlargement of the spleen. The spleen became normal in size without any special treatment. He noticed an erythematous thickened lesion on his abdomen about six years ago. The lesion gradually increased in size and became diffuse all over the abdomen, chest, back, neck and extremities. There were small nodules on the chin, lips and nose, and erythematous and annular lesions with thick crusts on the dorsum of the hands, forearms, feet, legs and knees. There was slight itching but no anaesthesia or deep analgesia. Pus was found on removing the crust of a lesion. Erythematous lesions were present on the glans penis and scrotum. The history of syphilis was negative. Most of the skin surface appeared dry, scaly and erythematous, but this condition was notably absent where the cloth was tied tightly round the waist. The

appearance is best understood from the accompanying illustrations.

Differential diagnosis.—There was a suspicion of syphilis owing to the presence of annular lesions, but

Fig. 3.—Skin of back of neck. A smear from the skin removed showed abundant Leishman-Donovan bodies.

that was ruled out as both the Wassermann and Kahn reactions were negative. Blastomyces was suggested, but the result of the examination by Dr. K. Banerjee, of the skin department, showed that there were neither fungi nor blastomyces. We took a smear from a lesion on the nape of the neck and from the annular lesions on the left ankle, left knee and left hand. Slides stained by the Ziehl-Neelsen method showed no acid-fast bacilli

Fig. 4.—Back of hand showing annular lesions.

but those stained with Leishman's and Giemsa's stains showed numerous *Leishmania donovani* and cocci, especially, diplococci.

The special points of interest in this case are the persistent diagnosis of leprosy, the annular lesions which are uncommon in dermal leishmaniasis, and the accompanying dermatitis. As we have mentioned above, this

dermatitis was absent where the skin was protected by the cloth tied tightly round the waist; it may therefore have been due to intolerance of the sun's rays.

Fig. 5.—Skin of chest magnified.

Our thanks are due to Dr. K. Banerjee for kindly doing the bacteriological examinations.

A LEECH IN THE NASAL CAVITY AND ITS REMOVAL

By D. R. KAPUR, L.M.S.

Assistant Surgeon, Mirpur, Jammu and Kashmir State

IN the year 1925 at Kishtwar, a lad about 18 years of age came to the hospital with the history that he had a leech in the right nostril. On examination nothing could be detected. A saline douche was ordered to be given through the left nostril with the direction that the patient should breathe with his mouth wide open. One pint of saline was thus used but with no result. Later the compounder suggested the indigenous method. A bowl full of water was brought and placed just below the right nostril. After three or four minutes the leech came down but it slipped back when being caught with a dissecting forceps. The bowl was again placed there and as soon as the leech appeared it was caught with a Spencer Wells forceps.

A CASE OF RABIES WITH AN UNUSUAL- LY LONG INCUBATION PERIOD

By S. S. HAJARE, M.B., B.S.

Good-Fellow Hospital, Palampur (N. G.)

A. P., a MAHOMMEDAN FEMALE, aged about 30 years, was bitten by a rabid dog on her right leg on 2nd September, 1931. She arrived at this hospital on the same day and the wound was carbolicised and dressed. She was sent to Ahmedabad Civil Hospital, the nearest centre for anti-rabic treatment. The patient before reaching the hospital at Ahmedabad had a fit which presumably was hysterical. This fit was translated by her attendants as the development of hydrophobia and so without taking any anti-rabic treatment the patient was brought back to her village. Thereafter she did not have any illness worthy of note and the wound of the dog bite completely healed.

On 10th November, 1932, she developed typical symptoms of hydrophobia and died on 12th November, 1932, after an illness of two days.

The interesting feature of this case is that the patient developed hydrophobia as much as 14 months after she was bitten by the rabid dog.

ACUTE INVERSION OF THE UTERUS*

By J. C. BHATTACHARJEE, L.M.P.
Sycotta Factory Hospital, Kharikatin, Assam

A COOLIE woman, Tanti by caste, aged 30 years, was admitted to the hospital at 4 p.m., on 14th October, 1932.

History.—The patient had just been delivered of her second child; the first child, now three years of age, was delivered naturally.

In the present case labour was short and delivery of the child successful. As the placenta did not come away at once the *dai* and others applied pressure over the abdomen, when they noticed a large mass protruding from the vulva.

On admission the patient was prostrated, with a pulse of 120 per minute, and temperature 97°F.

Examination.—The uterus was absent from its usual site and there was a hollow in the supra-pubic region.

A dirty mass, to which the placenta was partially attached, was found protruding through the vulva. It had a hard but elastic feel and there was not much bleeding. The vaginal mucous membrane was found to be continuous with the covering of the projecting tumour, the line of inversion being above the level of the cervix.

Treatment.—The protruding lump including the placenta was cleansed and bathed in hot lysol lotion. Then the placenta was peeled off gently. The inverted inner surface of the fundus was in partial view and was found to be ragged. Taxis was attempted, and after considerable difficulty, on account of uterine contractions occurring, the organ was successfully reduced. An intra-uterine lysol douche was given and the patient was also given an injection of ten cubic centimetres of puerperal antistreptococcal serum, with ergot and quinine by the mouth.

Puerperium.—The patient developed a mild degree of sepsis, running an intermittent temperature from normal to 101°F. from the next day, and the lochia were at first sanguineous and offensive but gradually became normal. She was given hot vaginal douches daily and every other day ten cubic centimetres of two per cent. acriflavine solution intravenously for four injections. She became completely afebrile from the 23rd October, and was discharged from the hospital on 26th October, 1932.

My thanks are due to Dr. D. Manson, M.B., Ch.B., Chief Medical Officer of the Jorehaut Tea Company, for his advice and his kind permission to send this note for publication.

A CASE OF TYPHOID FEVER WITH CEREBRAL SYMPTOMS

By A. R. MANSOOR, M.D. (Durh.),
D.P.H. (Eng. et. Edin.)

University Hospital, Aligarh

T. H., a male student, aged 17, was admitted into the University Hospital on the afternoon of the 26th of November, 1932.

Present history.—Complains of fever, cough, headache, backache and pain in the throat. Temperature 102.8°F., pulse 100, respiration 28, skin dry, tongue furred, throat congested, heart, lungs, liver, spleen and urine, show no abnormality, blood negative for malaria and other parasites, and shows no difference in corpuscular contents.

Previous history.—Had fever with rigors on the morning of the 25th, he had had no other illness since May 1932 when he suffered from malaria. Right up to the 25th he had been feeling absolutely fit, had had an ordinary motion on the previous day but none on the day of admission.

Treatment.—Calomel grs. 2 and sodium bicarbonate grs. 10 were given at night followed by saline in the morning. On the 27th and 28th diaphoretic and expectorant sedative mixtures were given. On the 29th he passed 10 motions, watery, yellowish, containing pieces of orange and a few shreds of mucus; on microscopical examination only a few *Entamoeba coli* were seen. Blood repeatedly negative for the last five days. Patient put on chlorine mixture.

On the 30th patient was restless, could not express himself, and there were sordes on the lips. In the afternoon he developed stupor and delirium. Blood taken in broth and bile media for culture. Given glucose and sodium bicarbonate by the mouth every 2 hours. In the evening the patient lost control over his anal and vesical sphincters. Bouts of delirium and stupor progressive.

1st December, 1932. Patient semi-conscious, refuses all nourishment, passing faeces and urine into bed. Intravenous saline 10 ounces given at 10 A.M. and then repeated at 12 noon. At 2-45 P.M. he felt intensely cold, had rigors and general cyanosis, pulse nearly imperceptible. Subcutaneous injection of digitaline and strychnine given.

2nd December, 1932. Stupor very slightly less; delirium the same, passed 8 motions into the bed, hot packs applied and 10 ounces of saline given intravenously. At 6 P.M. 2 pints saline administered per rectum. At 9 P.M. showed signs of consciousness, complained of pain on sites of injection, had violent fits of shouting, crying and restlessness which lasted throughout the night. Glucose and sodium bicarbonate repeated every 2 hours.

3rd December, 1932. Slight improvement, occasional glimpses of consciousness, wants tea, shouting and restlessness the same. Saline per rectum twice a day continued.

6th December, 1932. Condition after steady improvement for the last three days has retrogressed, toxæmia intense. Saline per rectum continued.

7th December, 1932. Toxæmia state practically over, definite improvement in the mental condition.

8th December, 1932. Pure culture of *Bacillus typhosus* isolated from the blood.

16th December, 1932. Steady improvement during the previous week, the patient recovered control over his sphincters for the first time.

17th December, 1932. A crop of blisters appeared over the front of the neck and over the front of chest and a few over the abdomen; culture from blisters taken. After 48 hours' incubation the culture medium was found to be sterile. On the 20th all blisters dried up leaving a fine powdery desquamation.

The temperature commenced to decline permanently towards the normal from the 24th, convalescence commenced from the 6th of January, and the patient was discharged as cured on the 11th.

A CASE OF NEURASTHENIA APPARENTLY CURED BY A DIET OF GHEE*

By R. K. BASU, L.M.S. (Cal.)

Medical Officer, Dumraon Hospital, Dumraon

A HINDU Brahmin, a lawyer by profession, aged 70 years, noticed the onset of the following symptoms in July 1930.

Both his mental and physical vigour gradually deteriorated until he finally lost all interest in life, both in his work and pleasure.

His appetite was poor and he suffered from obstinate constipation, but apart from these symptoms no physical cause for his condition could be discovered in spite of examination by numerous doctors.

As he was not improving he finally consented, on the advice of friends, to consult a Kaviraj practitioner in Calcutta. The patient did not go to see the practitioner but sent a detailed written history of his case and after

* Rearranged by the Editor.

* Abstracted by Editor.

study of this a small white powder was prescribed which had to be mixed with two drops of good ghee and taken every morning. In addition the patient was ordered to take at least one ounce of good ghee with rice both morning and night, and was told that all his vegetable curries must also be prepared with ghee.

These instructions were closely followed and the patient gradually increased the amount of ghee until he was taking about two ounces with each meal by the end of a fortnight. He now began to feel distinctly better and within two months he had gained ten pounds in weight and felt normal in every way.

Later, the amount of ghee was further increased until he was eating and enjoying three to four ounces with each meal. When I saw him nearly two years afterwards he was vigorous both mentally and physically and apparently completely restored to health.

This man was a highly emotional individual and I am of the opinion that mental disturbances had an effect on his endocrine system in some way, which upset his metabolism and the diet of ghee apparently restored this upset balance.

This case is of considerable interest in that it shows how important a part diet may play in effecting a cure. This is an aspect often ignored by some allopathic physicians who are inclined to rely too much on drugs alone.

In India the question of obtaining a diet sufficiently rich in vitamins is of extreme importance and I feel sure that great improvement in the general well-being of the people would be brought about if doctors were to pay more heed to diet and to learn which easily available articles of food contained the needed accessory factors.

CHORIO-EPITHELIOMA OR DECIDUOMA MALIGNUM

By J. M. DAS, L.M.S.

Teacher of Midwifery, Campbell Medical School, Calcutta

In my gynaecological and obstetrical practice I have seen and dealt with many cases of vesicular mole (hydatidiform degeneration of the chorion). Out of these I have seen four cases of a malignant nature—they are known as perforating or malignant hydatidiform mole or chorio-epithelioma and are sometimes called deciduoma malignum though it is a misnomer.

1st case.—In the year 1910 Lieutenant-Colonel C. R. McQueen, I.M.S., while Surgeon Superintendent of the Eden Hospital diagnosed a case of multiple fibroid, and when he opened the abdomen a branching brush-like growth was found perforating the uterus. He had to do total hysterectomy. I assisted at the operation.

2nd case.—About six years ago an Anglo-Indian patient was admitted in my ward in the Campbell Hospital and diagnosed as a case of vesicular mole, and I evacuated the uterus by dilatation and evacuation with a blunt flushing curette. She was discharged from my ward. In a month's time she came back, having irregular hæmorrhages and I curetted her and the scrapings were microscopically examined but there was no sign of chorionic cells or malignant proliferation. She was discharged after a month and a half, and subsequently admitted to the Eden Hospital where Lieutenant-Colonel Leicester, I.M.S., curetted her twice

and eventually had to do total hysterectomy as the bleeding continued. The specimen which is at the Eden Hospital shows a nodular growth on the fundus of the uterus.

3rd case.—About five years ago a patient was sent from the out-patient department having bleeding after a miscarriage of two months, in her home. She said she had passed many cauliflower-like growths and eventually the uterus became small but the bleeding continued. I scraped the uterus. The scrapings were examined and reported as chorio-epithelioma. I attempted vaginal hysterectomy but at the slightest touch of the knife she bled very freely. I sent her for radium treatment and after deep x-ray and radium needles insertion she was examined by me and I found her cured, leaving only scar tissue. The bladder was not affected. She is still under the observation of the radiologist and there is no sign of recurrence.

4th case.—This specimen I have demonstrated before the members of the British Medical Association (Bengal Branch). I removed it on the 7th of December 1932.

Patient, a Bengali, primipara, aged 25, admitted on the 18th of August. History of three months' amenorrhœa but the size of the tumour is about six months' pregnant uterus.

The case was diagnosed as vesicular mole and the following is the case history.

Admission—18th August, 1932.

30th August, 1932. (1) Evacuation of the uterus for vesicular mole—blunt flushing curettage; a large bucket full of the typical growth came out.

21st September, 1932. (2) Curettage again as the patient was bleeding off and on since the first evacuation.

27th September, 1932. (3) Examination—(a) Slight blood discharge. (b) Cystic mass on the left side.

It was diagnosed as chorio-epithelioma with cystic left ovary. As the patient was very weak with continuous malaise and slight fever, an operation was impossible and the general condition had to be improved.

7th December, 1932. Patient was operated on and total hysterectomy was performed and a cystic left ovary removed. The uterus which was bulky and retroverted contained a typical mass of chorio-epithelioma growth.

This case illustrates the importance of keeping vesicular mole cases under observation.

Special Article

NOTES ON INDIAN PLAGUE RATS

By W. J. WEBSTER, M.C.

MAJOR, I.M.S.

In the literature on plague there are several examples of the same rodent being referred to under different names. Changes in scientific names are of course unavoidable with advances in classification and adherence to the law of priority. A certain amount of information on the classification of rodents should be familiar to health officers and others who have to deal with plague outbreaks. It has been considered desirable to collect the essentials in this paper as they are not available without considerable study of the literature.

The nomenclature of certain rodents

The generic name 'Mus' used by Linnaeus (1758) applied not only to rats and mice but covered a multitude of rodents including guinea-pigs. The long-tailed house rat was then

known as *Mus rattus*. Trouessart (1881) introduced the name *Epimys* for rats and *Mus* was restricted to mice. Hollister (1916) noted that *Rattus* (Fitzing, 1867) had priority over *Epimys*, and the former has since been further referred back to Fischer, 1803. *Rattus rattus*, L., is therefore, the accepted name among English-speaking naturalists. *Mus rattus* is, however, still used by Italian writers and *Epimys rattus* continues to be recognised by French naturalists.

The sewer or ship rat was formerly known as *Mus decumanus* (Pallas, 1778) and was later referred to as *Epimys decumanus* or *E. norvegicus*. The correct designation at present is *Rattus norvegicus* (Erxleben, 1777). The other names may be encountered in current continental literature.

The so-called 'black' rat (*Rattus rattus*) may be brown and the 'brown' rat (*Rattus norvegicus*) may be black, and either may be grey. The description 'brown' has been applied to both and in Holland *norvegicus* has been called 'blue' (Jorge, 1928). These descriptions should be completely abandoned.

The name 'Mus' has been further restricted to house mice proper by the reintroduction of the genus *Leggadina* for field mice (Thomas, 1919). *Mus dubius* should now be named *Mus urbanus* (Wroughton and Davidson, 1920).

Blanford (1888) included bandicoots and mole rats under the generic name *Nesokia* or *Nesocia*. Thomas (1907) restricted *Nesokia* to the short-tailed mole rats of northern India. He introduced the name *Gunomys* to distinguish the long-tailed southern mole rats and revived the name *Bandicota*. Hence the confusion regarding *Nesokia bengalensis*. According to Wroughton (1908) the spelling *Nesocia* used by Blanford was without authority.

The identification of certain rodents

Rattus rattus belongs to the Order—Rodentia, Sub-order—Simplicidentata, Family—Muridae, Sub-family—Murinae and Genus—*Rattus*.

The Order Rodentia is distinguished from all other placental mammals by the two chisel-like central incisor teeth in each jaw. In the Sub-order Simplicidentata there is only one pair of upper incisor teeth while the Duplicidentata (hares and rabbits) have two pairs.

Muridae have only sixteen teeth, viz, two incisors and six molars in each jaw (formula 1003). About one thousand and three hundred species and varieties of Muridae have been described. The Family Muridae has to be distinguished—in India—from the squirrel family and the bamboo-rat family. Squirrels can be distinguished in doubtful cases by the presence of pre-molar teeth and the fact that the tibia and fibula are separate. Bamboo rats have very small ears and eyes and the limbs and tails are short. They are found in Burma, Assam and the Himalayas. The fourth family, the porcupines (Hystriidae), is easily recognised.

Murinae have sparsely-haired tails longer than half the head and body together, and the worn teeth show bands, either straight or curved, running transversely across the biting surface. Murinae have to be distinguished from members of the Gerbillinae sub-family which have a long hairy tail, usually tasselled, and from the Cricetinae (hamsters) which have a very short tail, less than half the length of the head and body together, and which in the Indian area are confined to high altitudes in the north.

To put it very briefly, the teeth of rats and mice number sixteen including chisel-shaped incisors, while the tail is practically hairless and longer than half the head and body together. Attention to these points would prevent confusion with animals having an outward resemblance to rats and mice, such as musk rats of the Order Insectivora and mongooses of the Order Carnivora.

Keys to twenty-three genera of the Murinae and to the species of these genera are given in the summary of the Indian Mammal Survey by Wroughton (1919). He gives twenty-one species of *Rattus* but apart from *Rattus rattus* the only species likely to be met with in the plains is *R. blanfordi* with the distal part of the tail white and with only six teeth. Hinton (1918) describes twenty-two members or sub-species of the *Rattus rattus* group.

Most places in India provide at least two members of the *R. rattus* group. In Bombay, for example, it is easy to select black or white-bellied or brown varieties but some specimens appear to be intermediate between these. Even if it were practicable in plague work, there is

			Length of head and body in inches	Length of tail as percentage of head and body length	Number of teeth	Characteristic noise
<i>R. rattus</i>	6-8	about 125 (100-150)	10-12	a series of squeaks
<i>R. norvegicus</i>	about 10	about 90	12	a prolonged squeal
Bandicota	over 9	about 90	12	a snarl
<i>Gunomys</i>	less than 9	more than 66	(may be 10)	a grunt
<i>Nesokia</i>	less than 9	less than 66	16-18 8	..

probably no advantage in distinguishing the sub-species. For practical purposes the colour may be ignored.

In the important genera *Rattus*, *Bandicota*, *Gunomys* and *Nesokia*, the anterior upper molar tooth measures not more than half the tooth row. In the genus *Rattus* the worn areas on the molar teeth are distinctly curved while in the other three genera mentioned these laminae are practically straight.

Some of the points useful in identification are given in the table. Other characters are:—

(a) *R. rattus*—tail of uniform colour showing about two hundred and fifty rings and a tiny tuft of hairs at the tip; ears and eyes large; top of skull shows an area shaped like a tennis racquet, the temporal ridges being convex outward. (b) *R. norvegicus*—tail often lighter below with about two hundred and ten rings less well marked than in *rattus* and a tiny tuft of hair at the tip; eyes and ears small; temporal ridges almost straight and parallel; soles of feet usually pinkish. (c) *Bandicota*—tail thick and blunt and shows rings; head narrow; long spinous hair all over body. (d) *Gunomys*—tail rather like that of *rattus* but rings less well marked and no tuft of hair at tip; spinous hair on back; head broad; palatal foramen long (about 8 mm.). (e) *Nesokia*—head broad; palatal foramen short (about 5 mm.).

Some of the other genera may be dismissed briefly. In mice of the genera *Mus*, *Leggada* and *Leggadilla* the anterior upper molar tooth measures more than half the tooth row. *Leggadilla* has well-marked frontal ridges while *Mus* and *Leggada* have none. The frontal ridges can be palpated through the skin on top of the head; they diverge backwards from just behind the eyes. *Leggada* is a jungle genus with a longer muzzle than *Mus*. The metads (genus *Millardia*) have less than six plantar pads. Bush rats of the genus *Golunda* have grooved incisor teeth. In the genus *Vandelluria* there is a flat nail, instead of a claw, on the first and fifth digits of all four feet.

The other thirteen genera are not widely distributed and are mostly confined to further India and the Himalayas. For the identification of these genera the tables quoted must be consulted. In some cases the location of the capture is a guide to the specific name. In many cases distinction depends on variations in colour which are not easily appreciated without specimens for comparison. The real colour is, of course, seen only in fresh specimens, and should be noted before preservation. Methods of measuring, skinning and preserving small mammals are given in a pamphlet entitled 'Instructions for Collectors: No. 1—Mammals' issued by the British Museum (Natural History).

Rattus norvegicus

Wroughton (1919) states that there is no authentic record of the taking of *norvegicus*

in India outside the docks of seaside towns. As *norvegicus* is common in Bombay where most of the investigations of the plague commission were carried out, somewhat undue stress has been laid on the importance of this species in Indian plague. Patton (1931) states that chronic plague persists in *norvegicus* in Bombay as in most parts of India (the italics are mine), and proceeds to explain that the epizootic begins in the young *norvegicus* population. Owing to the strictly limited distribution of *norvegicus* this explanation is misleading. As a result of the supposed importance of this species, those who have had occasion to examine rats in India have been too anxious to identify *norvegicus* and I know of several instances where the name was wrongly applied. One rat known only in Nepal has a superficial resemblance to *norvegicus* but is now named *Rattus rattus brunneus* (Hinton and Fry, 1923).

Plague rodents in public health work

As a result of its numerical density, wide distribution and domestic habits, coupled with its specific flea infestation *Rattus rattus* is by far the most important species of rat as far as plague in India is concerned. *R. norvegicus* is certainly of importance in Bombay. In Calcutta which has scarcely suffered from plague (perhaps because the rat flea index there is very low and mainly due to *astia*) *norvegicus* formed 88 per cent. of the rats examined in connection with the recent survey (Strickland and Roy, 1930). These two species should be identified definitely. Examples of *Bandicota*, *Gunomys* and *Nesokia* should at least be recognised as such, to avoid confusion with *rattus* and *norvegicus*. Other rodents should be identified if possible when plague infected or when they harbour unrecognised fleas. Plague infection of rodents other than the Murinae (e.g., hares and squirrels) and in fact of mammals other than rodents may occasionally be met with. This, however, appears to be much less important in India than in other plague-infected countries.

THE CLASSIFICATION OF THE ANÆMIAS

A MEDICAL man returning to civilization after an absence of 15 years would receive many shocks; not the least amongst these would be when he encountered an article in a recent medical journal on some disease associated with anæmia. He would naturally find that he was a little out of date and would turn with confidence to a recent edition of some standard textbook on medicine, and then his real trouble would begin. He would encounter the familiar opening, 'Anæmias can be divided into two groups, primary and secondary; the primary anæmias are chlorosis and pernicious anæmia; secondary anæmias do not arise spontaneously, but are the result of other pathological processes, etc.'. He would read on and find that little was said about chlorosis, except that the disease had practically disappeared, and that so much is now known about the 'other pathological processes' that result in pernicious anæmia that he would wonder why the definition of a secondary anæmia could not be applied to it; he would read still further and find that despite the great advance that had been made in our knowledge of anæmias there was still considerable doubt as to the nature of the 'other pathological processes' to which some of the secondary anæmias were secondary. In a state of mental confusion he would put the book down and would ask himself why the writer of the textbook had not had the courage of his obvious convictions and given a new classification of the anæmias.

The answer to this question is evident; during the last few years the inadequacy of the old classification has been fully realized and every hæmatologist has attempted to supply a new one, but no classification has yet been suggested that will satisfy the majority. Consequently, writers of textbooks that are primarily for the use of the undergraduate student will not take the responsibility of adopting any one of these new classifications; they fall back on the old one and try to make the best of it.

It cannot be said that any great advances have been made in the technical side of hæmatology during the last few years—especially if we exclude the intra- and supra-vital staining methods which are applicable mainly to the leucocytes—but new emphases have been applied to different aspects of the subject; for example, the hæmatocrit is not a new instrument and red blood cells have been measured from the time of van Leeuwenhoek,

but the emphasis which has been laid by recent workers not only on the mean size of red blood corpuscles but also on the dispersion round that mean has led to a very distinct advance in our understanding of certain anæmic states.

One of the newer methods of classification is according to the size of the red cell; we have macrocytic anæmia—of which the typical example is pernicious anæmia, normocytic anæmia—which includes true secondary anæmia (that is anæmia following acute hæmorrhage) and certain aplastic anæmias, and microcytic anæmia; the last-named group is divided into simple microcytic—the orthochromic anæmia associated with chronic disease, and microcytic hypochromic, in which are included simple achlorhydric anæmia and the anæmia following chronic hæmorrhages. This classification has the advantage of extreme simplicity; it probably appeals to the medical student and to the amateur hæmatologist who, equipped with an halometer and a Talqvist scale, is now prepared to give an 'authoritative' opinion on any case of anæmia.

It is not however a very helpful classification as it gives no indication as to the ætiology of the various anæmias, and a classification is required which takes some account of the pathological processes which bring about the conditions. A very clear exposition of our present knowledge regarding anæmias was given by Dr. Witts in last year's Goulstonian lectures; the lecturer himself has contributed no small part to the recent advances in this subject. Though he has not supplied a summarized classification he has dealt with the subject from the ætiological aspect, and we feel that no classification which does not take this aspect into account will be satisfactory. The following, which is mainly based on the teaching contained in these lectures, is an example of such a classification:—

(a) *True secondary anæmia* due to loss of blood either from the skin, from mucous or from serous surfaces; this loss may be acute or chronic, and the anæmia is accordingly normocytic orthochromic or microcytic hypochromic.

(b) *Anæmia due to errors of erythropoiesis*; these may be due to:—

(i) Aplasia or hypoplasia of toxic or mechanical origin.

The anæmia here is caused by a functional failure of the bone marrow; it is normocytic and usually orthochromic. It may be brought about by long-continued septic processes, by chemical poisons such as arsphenamin, by exhaustion of the bone marrow as a terminal condition in other anæmias especially pernicious anæmia, or by displacement of the bone marrow by proliferation of non-erythrocytic tissues.

(ii) Dysplasia.

Under this heading are the deficiency anæmias, on which there has been so much important work done recently. The anæmia may be

macrocytic or microcytic according to whether the blood formation has been checked at the megaloblastic stage, as in pernicious anæmia and the specific anæmia of pregnancy by the absence of 'Castle's intrinsic factor' and vitamin B, respectively, or at the normoblastic stage, as for example in simple achlorhydric anæmia, the nutritional anæmia of infancy, and the anæmia of sprue, which are caused by deficiency of, or failure to absorb, iron, vitamin C, etc.

(c) *Anæmia due to errors of erythrolysis*; these can be divided into :—

(i) Anæmias due to defects in the red cells themselves; they may be of congenital origin, or caused by parasitization or hæmolytic poisons, either chemical or biological.

(ii) Anæmias due to hyperfunction of the tissues responsible for the disposal of obsolete red blood cells, the reticulo-endothelial cells in the spleen and elsewhere.

The nature of this anæmia will be influenced by a number of factors, according to whether the blood destruction is acute or chronic, and according to the way the bone marrow reacts. If there is a sudden destruction of red blood cells the reaction of the bone marrow may be so brisk that not only will there be large numbers of reticulocytes but there may also be macrocytes and even nucleated red cells in the peripheral blood; however, the usual blood picture is a normocytic orthochromic anæmia. Other changes which accompany increased blood

destruction will also vary according to the acuteness of the hæmolysis, from hæmoglobinuria and jaundice to simple urobilinuria.

It is true that there are anæmias which we have difficulty in placing in a classification like the above, but this is not the fault of the classification so much as of knowledge of the ætiology of the disease. As our knowledge advances there is no doubt that from time to time anæmias that have been classed in one group will be moved to another group; a recent example of this has been pernicious anæmia. For many years this disease has been considered to be a hæmolytic anæmia; we were misled by the presence of abnormal quantities of the products of hæmolysis, urobilin and stercobilin, in the urine and fæces. We now know that these were evidence not of increased blood destruction but of the inability of the organism to utilize again the normal products of hæmolysis, and that pernicious anæmia is due not to an error of erythrolysis, but to an error of erythrogenesis. If liver is given in a case of pernicious anæmia, erythrogenesis again proceeds normally and excessive bilirubin excretion ceases.

Rapid advances have been made in our knowledge of hæmatology during the last few years, and we feel that, for the sake of the rising generation of medical students as well as for their teachers and examiners, the time has now come when these advances should be consolidated by the adoption of some new standard classification for the anæmias.

Medical News

EXTRACTS FROM THE MINUTES OF A MEETING OF THE BENGAL COUNCIL OF MEDICAL REGISTRATION HELD ON THE 18TH AUGUST, 1932.

NOTIFICATIONS announcing the appointment of the undermentioned gentlemen as members of the Bengal Council of Medical Registration were recorded:—

Name	In place of
(a) Lieut.-Col. Sir Hasan Suhrawardy, Kt., I.T.F.	Dr. R. V. Clayton.
(b) Lieut.-Col. C. R. Rai Sahib O'Brien, I.M.S.	Dr. Satishchandra Ghosh, I.M.S.
(c) Major T. H. Thomas, I.M.S.	Major S. J. V. Fox, I.M.D.
(d) Lieut.-Col. T. C. Boyd, I.M.S.	Lieut.-Col. D. P. Goil, I.M.S.

Government letter conveying sanction to the levy of a charge of Rs. 5 for incidental expenses of this Council from practitioners registered in other provinces on their admission free of fee to the Bengal Medical Register was recorded.

Notification announcing the appointment of Dr. B. N. Ghosh, representative of the Bengal Council of Medical Registration and the Governing Body of the State Medical Faculty of Bengal as a member of the Sanitary Board, Bengal, was recorded.

The following two gentlemen being representatives of the Bengal Council of Medical Registration and the State Medical Faculty of Bengal were re-nominated as

members of the Bengal Sanitary Board for a fresh term:—

1. Dr. B. N. Ghosh, L.M.S., F.R.F.P. & S.
2. Dr. T. Ahmed, M.B., D.O.M.S., F.R.C.S.

Order of the Government of Bengal accepting the reciprocity of registration in Bengal, of practitioners registered in Madras was recorded.

The Council decided that all registered practitioners be informed that in the opinion of the Council certificates of death might legitimately be granted by registered practitioners only when they were actually present at the time of death of the patients or saw the deceased very soon after death.

Dr. Kedarnath Das, C.I.E., M.D., F.C.O.G., moved that the following institutions should be inspected before the next meeting of the Council:—

- (a) Dacca Medical School.
- (b) Mymensingh Medical School.
- (c) National Medical Institute.
- (d) Calcutta Medical School.
- (e) Jackson Medical School, Jalpaiguri.
- (f) Chittagong Medical School.

The motion was approved.

An application from the Superintendent, Bengal Medical Institution and Hospital, Beliaghata, praying that the institution be granted affiliation to train students for the licentiate examinations of the State Medical Faculty of Bengal was considered and the superintendent was requested to furnish particulars of the institution in the form of return prescribed by the Council.

The Council recorded reports of two prosecutions under Section 6 of the Indian Medical Degrees Act, 1916. The amount of fine imposed by the Court is noted against each name—

1. Manicklal Mukherjee—Sentenced by the Sub-Divisional Officer, Bongaon, to a fine of Rs. 35.
2. S. A. Rahman—Sentenced by the Magistrate of Scaldah, to a fine of Rs. 5.

THE GODAVARI DISTRICT MEDICAL ASSOCIATION, COCANADA. FIRST ANNIVERSARY CELEBRATION.

THE First Anniversary of the above Association was celebrated on the 18th February, in the premises of the M. S. N. Charities Buildings, Cocanada, under the presidency of Rao Bahadur Dr. T. S. Tirumurti of Vizagapatam. 85 members, including a number of lady doctors, and 23 non-member doctors attended the function from all over the district, including 3 from West Godavari. Major T. S. Shastry, I.M.S., was elected as president, Drs. Audinarayanaswami and Kamaraju as joint secretaries, and Dr. Miss T. K. Narayanaswami, Dr. S. Swami Naidu of Rajahmundry and Dr. B. S. S. Prasada Rao of Samalkot as members of the managing committee for the new year. Rao Bahadur Dr. T. S. Tirumurti, after expressing his great pleasure at the large attendance, delivered a very interesting and instructive lecture on 'Some Recent Advances in our Conceptions and Diagnosis of Disease'. Major Shastry then talked about the necessity of conducting a leprosy campaign in this district and exhorted all the members of the Association to co-operate in their respective areas when the campaign was organised; other members took part in the discussion.

FIFTY YEARS AGO

(From the *Indian Medical Gazette* of April, 1883, Vol. XVIII, pp. 104, 99 and 105)

THE observations and researches of Dr. Patrick Manson of Amoy, regarding the life history of *Filaria sanguinis hominis* and the pathology of the diseases associated with it, are well known. In a recent paper published in the *China Customs Gazette*, he addresses himself to the elucidation of the apparent paradox, that, while in the majority of cases in which the blood is found to be infested with embryo filariæ no pathological disturbance of any sort is discernible, in a certain

number phenomena indicative of impeded lymph flow through the glands exist. It is important to recollect that the parent worm inhabits the lymphatics on the distal side of the lymphatic glands, and that the embryos swarm into the blood by passing through these glands. Why is it that in most cases this migration is accomplished without irritation of either the glands or the lymphatic vessels (afferent) beyond them; while in a few much irritation of both is abundantly manifest, and gives rise to painful enlargement of the glands and dilatation of the vessels, with effusion of lymph on the surface or into the surrounding tissues, the result eventually being hyperplasia of the lymphatic area implicated? His explanation of the anomaly is, that normally the parent worm is viviparous, and ejects from its uterine sac embryos which have uncoiled themselves and stretched their investive chorionic envelope so as to form a closely fitting outer garment corresponding in shape to that of the embryo, and not impeding its movements; whereas in certain cases the parent worm aborts—is oviparous—and discharges circular ova in which the embryo remains coiled in the chorionic envelope which it is unable to stretch. The diameter of the circular ovum is greater than that of the filiform embryo ($\frac{1}{250}$ to $\frac{1}{500}$ against $\frac{1}{3,000}$); and no aid in propulsion is gained from the active movements of the latter.

* * *

Quinetum the well-known 'Cinchona febrifuge', it is to be remembered, represents the whole of the alkaloids of the *Cinchona succirubra* bark, the proportions being approximately as follows:—

Quinine	4½ to 6 per cent.
Cinchonidine	24 " 30 " "
Cinchonine	38 " 45 " "
Amorphous alkaloid	14 " 21 " "

* * *

The Surgeon-General, H. M.'s Forces in Bengal, has issued a warning to officers commanding regiments, that an epidemic of cholera is about to take flight from Bengal and wing its way up the Gangetic plain. Precise dates of its anticipated arrival at particular stations are given. We hope that this warning may prove to be a needless one. No harm can come of putting the authorities on the alert, but announcements of this kind should be cautiously made to avoid creating panic.

The Treatment of Some of the Commoner Skin Diseases

By R. M. B. MacKENNA, M.D. (Camb.),
M.R.C.P. (Lond.)

(Abstracted from the *Medical Press and Circular*,
December 14, 1932, p. 487)

IMPETIGO CONTAGIOSA

THE standard casualty department treatment for this is dilute nitrate of mercury ointment applied copiously. Impetigo is an acute infection of the skin with streptococci and/or staphylococci, and is characterised by the effusion of a copious sero-purulent exudation from the affected area. If the usual mercurial ointment is applied on lint, it forms a waterproof covering under which the exudation may spread, thus infecting adjacent areas. Further, the fatty base of the ointment retards the normal heat loss from the skin, the temperature of the covered area rises slightly, the openings of the sweat and sebaceous glands are dilated, and a very fertile soil is prepared in which the cocci may increase and multiply in warmth and comfort. Cases of impetigo caused by

relatively innocuous strains of bacteria may respond to the standard treatment with dilute nitrate of mercury ointment, but if the infecting organisms are of a virulent nature, or the resistance of the patient is low, the condition of the patient rapidly goes from bad to worse. Good results may be obtained by the following line of treatment:

- (1) Remove the crusts either by softening them with olive oil, or by the application, for six or eight hours, of a starch and boracic poultice.
- (2) Apply the following lotion six or eight times daily:

R̄ Sulphuri precipitati	..	gr. ii
Ichthyol	gr. iii
Calaminæ preparatæ	..	gr. lx
Zinci oxidi	gr. xxx
Glycerinæ	ʒ. x
Aquæ calcis	ʒiv
Aquam ad	ʒi
M.		

- (3) Remove the crusts regularly once every thirty-six hours.

(4) When the exudation ceases, and the only symptom is slight redness of the affected areas, apply the following ointment twice daily:

R Hydrargyri ammoniati .. gr. v
Paraffinum molle 5i

It will be seen that the rationale of this line of treatment is to soothe the inflamed areas with a modified calamine lotion, to increase the formation of crusts, so that the exudation is localised, and to apply the lotion so frequently that the ichthyol and sulphur, and to a lesser degree the other ingredients, can exert their antiseptic action on every drop of exudate. Cases which do not respond to this line of treatment frequently respond quickly if the following lotion is applied freely four times daily to the affected parts:—

R Hydrargyri perchloridi .. gr. 4
Spiriti methylati industrialis .. 5fs.
Glycerini m. v
Aquam ad 5i

Never forget the impetigo in children, commencing on the ears or in the scalp, is usually secondary to pediculosis capitis. If lice or nits are found, and the impetiginous eruption is at all widespread over the scalp, the best line of treatment is to cut the hair short, and apply compresses of perchloride of mercury lotion (*vide supra*) thrice daily to the scalp.

Furunculosis.—Furunculosis is a disease caused by cocci, and frequently is difficult to eradicate. We should remember that in all cases of boils the urine must be tested before treatment is commenced. Even if there is no sugar in the urine the patient will benefit if his intake of carbohydrates is halved, and spicy foods, should be taboo. There is one point with regard to furunculosis which is not usually emphasised, and that is that an attack of boils commonly develops after several months, or even years, of self-neglect, and unless the patient's life is regulated from all aspects, furunculosis frequently becomes distressingly chronic. The house surgeon, during the last weeks of his appointment; the student or the nurse working for his or her examinations; the school-mistress, towards the end of term; the adolescent struggling with higher school certificate, a mass of unresolved sex complexes, and the frequent over-strain of team games; the typist or clerk who is habitually constipated and never takes exercise; the workman who suffers from chronic under-nourishment, and lacks personal cleanliness—all these are types which often give a history that they started to have boils, and despite much treatment, the boils have continued to erupt—often in crops—from time to time. If the physician is content merely with the usual local and tonic treatment, the condition of the patient frequently goes from bad to worse. Frequently the patient herself is her worst enemy. The stenographer will indignantly state that she is getting at least an hour and a half exercise in the open air daily, looking after her bowels, and doing all things as she has been directed, and yet she is not better. She does not tell you that she smokes fifteen to twenty cigarettes a day, frequently takes aspirin in large doses, invariably reads in bed until one o'clock in the morning, and never sleeps with her window open. Similarly, the workman will conscientiously go to the local bath-house thrice a week, and even have potassium permanganate baths, but if we have forgotten to warn him that it is no use attempting to disinfect the skin in this way, when on leaving his bath he dons an old and unwashed woollen vest on which is the coagulated excretion from the half-dozen boils from which he has previously suffered, then he will continue to suffer from furunculosis. These matters seem so simple that they are seldom referred to; frequently, however, persons go on from month to month suffering from boils or carbuncles, and if the physician would only discuss fully his patient's habit of life, he would discover and be able to rectify apparently trivial matters which are frustrating the whole of his treatment.

The local treatment of furunculosis has been so thoroughly dealt with in various recent publications that I intend only to make brief reference to it here. The most modern line of treatment is by solutions containing antiviral, or jellies containing bacteriophage. For boils of the external auditory meatus, gauze plugs soaked in antiviral solution and changed three or four times daily are excellent, and I have had good results from packing the cavities of carbuncles with bacteriophage jelly; but for the average case of furunculosis it has been my experience that the benefit obtained by the use of polyvalent staphylococcal antiviral is in no way commensurate with the high cost of treatment. For the majority of cases I prefer to give non-specific therapy in the form of intramuscular injections (once weekly) of 1.5 c.c. butyrate of manganese, or collosol manganese in the increasing doses recommended by the makers; concurrently, most cases benefit if given two tablets of oxide of tin (stannoxyl) thrice daily before food, and a drachm of Easton's syrup (B.P., 1914) thrice daily after food. Many authorities prefer to use vaccines rather than the preparations of manganese; an auto-genous vaccine is frequently excellent; stock vaccines are successful in some cases.

Erysipelas.—One of the most dangerous diseases due to cocci is erysipelas; facial erysipelas frequently ends fatally. Recent work has indicated that injections of milk frequently benefit apparently hopeless cases. One such case particularly impressed me; the case was one of facial erysipelas following a graze on the bridge of the nose in a man of sixty years of age. Despite the subcutaneous injection of large quantities of both polyvalent anti-streptococcal serum and anti-scarlatina serum, the patient's temperature had for a week swung between 101° to 103°; both cheeks, eyelids, and the forehead were affected, and the spreading edge of the eruption was travelling rapidly over the scalp. At 1-30 p.m. on the seventh day of the illness, 10 c.c. of aolan (detoxicated milk protein—Beiersdorf) were injected intramuscularly. By 8 p.m. the patient's temperature had risen to 105°, but during the night the temperature dropped to normal, and although no further injections were given, the temperature did not again rise, and the eruption rapidly disappeared.

Fresh milk may be prepared for injection by boiling for four minutes, cooling to body temperature, and straining through sterile gauze. Sayed has had good results by the intramuscular injection of 10 c.c. of milk in cases of facial erysipelas, and also claims that 'intra-dermal injections of sterile milk made parallel to and about 1½ inches away from the spreading margin of erysipelas produce a local reaction which prevents further extension of the infection at the site of injection, and improves the condition elsewhere'.

Supplies of serum may be difficult to obtain in some country districts, but there is usually an adequate supply of fresh milk, and the practitioner faced with an acute case of erysipelas may find that even if he cannot manage an intra-dermal injection, an intramuscular injection of milk may influence very favourably a case which could otherwise give rise to much anxiety. If a case of erysipelas is going to respond to intramuscular injections of milk, usually only two or three injections are necessary, and many cases clear up after a single injection.

Sycosis.—Cases of coccogenic sycosis are frequently extremely resistant. Many cases will respond to the following line of treatment:

(1) Clean up the face carefully, puncturing any pustules, and expressing their contents. If a hair is visible at the centre of any pustule, remove it with a pair of forceps. Remove any crusts either by means of a starch and boracic poultice, or with olive oil.

(2) Instruct the patient to desist from shaving, but to keep the beard short by clipping or cutting with scissors.

(3) Fold some white gauze so as to make a pad about six layers in thickness, soak it well in the perchloride of mercury and spirit lotion (*vide supra*), and place this in close contact with the skin for half

an hour at a time, and instruct the patient to carry out this procedure thrice daily.

(4) Remove the gauze compress after the half-hour has elapsed, and apply either calamine lotion with 1 per cent. ichthyol, or the following ointment:

R̄ Hydrargyri ammoniati	..	gr. iv
Ichthyol	..	gr. iv
Paraffini mollis	..	ʒi

(5) If there is any blepharitis this must be treated on the usual lines, for the tear sac and the intra-nasal mucosa become infected with organisms washed off the eyelids by the tears, and the skin of the upper lip becomes constantly re-infected from these sources.

(6) General treatment includes avoidance of exposure to bright sunlight or cold winds; a wisely disciplined mode of life, tonics, and also a course of injections of butyrate of manganese.

If these measures fail, one may have recourse to such coal tar derivatives as acriflavine or brilliant green. Either may be used in an ointment (1 to 2 per cent.) or in a lotion (1 in 1,000). Some authorities recommend strongly alcoholic solutions of brilliant green. The following ointment, for the formula of which I am indebted to Dr. P. B. Mumford, occasionally cures cases of syccosis which have resisted other lines of treatment:

R̄ Sulphuri precipitati	..	ʒi
Balsami peruvani	..	ʒi
Unguenti diachyli	..	ʒi
Paraffini mollis	..	ʒii
M.		

Sig.—Apply twice daily.

If these measures fail, then the practitioner will probably have to refer his patient to a dermatologist, who will decide whether or not the case is one which will benefit from epilation with x-rays, or from some other treatment.

Adenoids

By F. PEARCE STURM, M.D., CH.M.

(Abstracted from the *Practitioner*, November, 1932, Vol. CXXIX, No. 5, p. 560)

Functions of the respiratory tonsil

For many years I have been engaged in a clinical and pathological research upon the problem of the adenoid child. The evidence so obtained is overwhelmingly in favour of the conception of the pharyngeal tonsil as a protective mechanism for the respiratory tract, but here there is space only for a summary of a few points.

(1) The respiratory tonsil or adenoid acts as a test organ for the respiratory fluids, namely, the inspired air and the systemic blood-current. It takes samples of all atmospheric micro-organisms and prepares immunizing substances from them.

(2) It is a probable survival of the oosphadium or test organ of water-breathing animals, and undergoes a functional hypertrophy when the respiratory and circulating currents are contaminated.

(3) This functional enlargement, though protective in intention, now causes obstructive and other difficulties for evolution has built a palate which divides the simple primitive mouth into an upper respiratory and a lower buccal compartment, and the respiratory tonsil is confined within the narrow, bony limits of the former.

(4) Hypertrophy of the respiratory tonsil, though not a disease, but a purely protective reaction, becomes pathological and calls for surgical removal when its presence in the narrow confines of the nasopharynx causes a greater disability (aural or respiratory) than is counterbalanced by the increased physiological activity which is the purpose and result of the hypertrophy.

(5) There is abundant evidence that leucocytes, laden with captured bacteria, come to the germ centres of the tonsil for destruction. This observation applies also to

the faucial tonsils and to the appendix, which is an abdominal tonsil. The destruction of cells and bacteria within the germ-centres of the tonsil, and the subsequent involution and disappearance of the germ-centres, points to the conclusion that one of their functions is the manufacture of immunizing bodies generally. As the germ-centres increase in number and activity in diseases which are certainly not bacterial in origin (hypo-thyroidism, hypo-pituitarism, hypo-adrenalism, malnutrition and digestive disease in children) as my observations conclusively prove, it is probable that they also provide the organism with substances to neutralize the toxins of defective metabolism.

(6) When the ductless glands, owing to the absence of essential nutriment, are unable to manufacture a sufficiency of hormones, the pharyngeal lymph units hypertrophy. The most careful examination of many thousands of sections of tonsillar tissue removed from such cases reveals not the slightest evidence of bacterial invasion. This statement is not based upon an isolated observation. In the course of the research my co-worker, W. E. Cooke, has cut some 20,000 sections from pharyngeal tonsils removed by myself. As a clinical cure is occasionally obtained in this particular type of hypertrophy by the administration of infinitesimal doses of iodine, it is possible that the organism attempts to force a simple lymph organ to do the work of complex endocrine glands which are functionally incompetent.

(7) Tonsillar hypertrophy constantly occurs at a time when the new-born child is not yet immunized; at a time, that is, when infection is most dangerous. Once immunization is effected both respiratory and alimentary tonsils normally tend to regress and disappear. As soon as the alimentary and respiratory tracts of the new-born infant are invaded by the innumerable micro-parasites which in the absence of immunity threaten existence, the lymphoid tissues, and particularly those of the respiratory tonsil, become enlarged, vascular and active.

Ætiology of adenoid hypertrophy

With regard to causes I shall confine myself to a brief summary of personal observations. Heredity is a predominant factor in about 50 per cent. of cases. Not only is it frequent to find the condition in several or all of the children of one family, but the facial appearance of one or both parents is often conclusive. The importance assigned to syphilis as a cause for adenoids by French writers is not confirmed. In one group of 600 adenoid children, there was one with specific nerve deafness, two with oxycephaly, twelve with true Hutchinson teeth, one with interstitial keratitis, but not a single case of septal osteitis, sabre-shin, or Hutchinson's syndrome of keratitis, notched incisors and nerve deafness.

There is no evidence that tuberculosis has any causal connection with adenoids, nor has there been any instance of an adenoid child with rickets. The skeletal deformities which afflict the adenoid child are chiefly confined to the respiratory framework; those of rickets are more generalized, involving the cranium proper and the bones of the pelvis and extremities. Breast-fed and bottle-fed children were about equal in number in more than one thousand cases, nor does sex appear to be a predominant influence, an equal number of boys and girls being affected.

Many children are born with adenoids. In such cases some or all of the following factors are usual:—(a) The environment of the mother during her pregnancy has been such that she has lacked a sufficiency of air and light; (b) her diet has been deficient in vitamins (particularly so-called fat-soluble A vitamin); (c) she has been subject to conditions which have produced extreme physical exhaustion, as, for example, having a bed-ridden relative to whom she attends in addition to working all day in shop or factory, doing her home work at night and taking in washing at the week-end. One or both parents and often grandparents are of the adenoid type.

Apart from heredity and such occasional determining causes as local or general infection, the common factor behind all cases of adenoid hypertrophy is malnutrition. The lungs of most of these children are fed upon the air-sewage of dark and badly-ventilated dwellings, and the diet is grossly deficient in essential food-factors. Not only the children, but the majority of the parents never eat butter, fresh eggs or unskimmed milk, and the cheapest fruit is an infrequent luxury. In many the diet is almost exclusively carbohydrate. Patent foods of the cheapest kind, fish and potato-chips fried in nauseating grease, together with butter substitutes and tinned carrion, form the diet out of which the physical bodies of many adenoid children and their ancestors have been built. Most of the diseases of humanity have been produced in animals by feeding them upon artificial foods.

Adenoid hypertrophy is a social disease, due to poverty, and the ignorance which accompanies poverty. Of the determining causes in any individual not actually born with the condition, the chief are the same as the predisposing causes, namely, improper food and foul air. In addition to these, or in their absence, the infectious diseases of childhood may act as determining causes in predisposed individuals. In a child in whom predisposition cannot be determined, any general or local infection which attacks the pharyngeal tonsil, as it might have attacked any other tissue of the body, is an accidental cause of the condition in another than the adenoid type.

Finally, with regard to the relative frequency of nasopharyngeal and faucial hypertrophy, in a series of 572 cases operated upon by the present writer, 15 had enlarged tonsils only, 282 adenoids only, and 275 both adenoids and enlarged tonsils. This preponderance of pathological conditions of the pharyngeal over those of the faucial tonsils, is an additional justification of the importance accorded to the former.

Treatment

During the past twenty years I have made many interesting observations on the purely medicinal treatment of adenoids. There is, to take one instance only, the effect of iodine. The minute quantity of iodine absolutely necessary for the harmonious working of the endocrine system is either absent from the diet of the adenoid child or cannot be assimilated in the form in which it is received. This deficiency may be partially rectified by the administration of infinitesimal doses of iodine, but only partially, for the condition depends upon more complex factors than the mere absence of this substance. Surgical removal is still the only efficient treatment, and will alone be described.

The indications for operation are too obvious to require elaboration. Whenever the pharyngeal tonsil becomes hypertrophied or infected it should be removed, irrespective of the patient's age. Failure to remove it results in the aural, respiratory and other disasters with which every practitioner of medicine is only too well acquainted. Apart from hæmophilia I know of no contra-indication.

In the present writer's opinion the La Force adenotome is the most efficient instrument that we possess for the removal of adenoid growths. I have used it in more than three thousand consecutive operations and have never had a hæmorrhage nor any other complication. A perusal of current laryngological literature proves that this happy immunity is far from being the lot of those who adhere to the curette. The La Force method, like any other surgical technique, has to be acquired. Failures to remove the growth by its aid are inconclusive, for they are merely evidence of an inaccurate technique, and in no way affect the results obtained by those who, after long experience, have abandoned all other instruments.

I have seen many failures of the popular curette to remove adenoids completely; the adenotome, on the other hand, never fails if correctly used. It removes the adenoid growth completely, usually in one piece,

and the removal is effected without injury to the pharyngeal mucous membrane or the Eustachian tubes. Pharyngeal trauma, with chronic sepsis and consequent ear disease, is a frequent result of curettage, and when the curette has been wielded by one of the many occasional operators who indulge in this operation upon the supposition that anyone can remove tonsils and adenoids the results are often more interesting than satisfactory. I instance only one woman recently seen at my out-patient clinic. Her soft palate had been torn through and her epiglottis damaged in an attempt to curette away her adenoids. This is an extreme case, but lesser degrees of injury are of frequent occurrence. Such disasters cannot be unusual; some such memory must have been in the mind of Dr. Dan Mackenzie when he wrote: 'In curetting excess of zeal is to be deprecated. There is no need to expose the pre-vertebral fascia, still less the bodies of the vertebræ'. He also writes: 'In the writer's opinion, the adenotome is unquestionably the best instrument', an opinion which is being shared by an increasing number of operators.

Failure to obtain perfect results with the La Force adenotome is due to one of two causes: (a) a faulty instrument; (b) an incorrect technique. Many of the adenotomes made in this country are wrongly constructed, particularly as to the angle of the adenoid box with the shaft of the instrument, which should be between 90° and 120°. If wider than 120° it is impossible to apply the instrument to the pharyngeal wall so that the whole of the growth is included in the box. Some adenotomes of foreign manufacture are made of inferior metal and must frequently be replaced; but they are usually correctly modelled and are often half the price of the incorrectly-modelled British instruments. Another disadvantage of some British adenotomes is the varied sizes of the blades; these should be interchangeable, but the blades made by one firm rarely fit the adenotomes made by another. To the laryngologist who removes adenoids as a daily routine this is a matter of importance. A correctly-modelled set of adenotomes, of British manufacture made to scale, with standardized blades, is an urgent need.

The faults of technique, which lead to failure when the instrument is of correct pattern, are two in number:

(1) The operator is so accustomed to the curette that he automatically makes a curetting movement with the adenotome as he pushes home the blade. This movement disengages the upper pole of the adenoid from the box. A portion of the growth thus escapes the cutting edge, and is left in the pharyngeal vault posterior to the upper edge of the vomer. This is the common fault of the inexperienced operator. It is not repeated when he realizes that the adenotome must be held absolutely motionless during the pushing home of the blade.

(2) The box of the adenotome must be pushed up into the vault of the pharynx. In order to effect this the shaft of the instrument must be maintained in pressure-contact with the incisors of the widely gagged lower jaw. If this contact of the shaft with the lower jaw is not rigidly maintained the instrument will fail to engage the upper portion of the growth.

Adenoidectomy by the La Force technique

(1) Under deep anaesthesia the gag is inserted to one side of the middle line of the jaw. If placed in the middle line, the thickness of the gag, one quarter of an inch, prevents the contact of the shaft of the adenotome with the lower jaw, and lowers the level of the box of the adenotome in the naso-pharynx by that amount.

(2) The operator palpates the naso-pharynx. He presses the folds of the adenoid growth together towards the middle, as one closes a half-opened book. He pushes any lower pharyngeal buds upwards, and any upper pharyngeal buds downwards, so as to crowd the contents of the naso-pharynx into a bunch which may be easily engaged in the box of the adenotome. At the same time he explores the lateral pharyngeal recesses (fossæ of Rosenmüller), breaking down any adhesions

about the torus of the Eustachian tube. These are sometimes so tough that the tearing of them is audible. They must never be curetted. If extensive, they may be rubbed away by a forefinger wrapped in gauze. Cutting or curetting may lead to incurable deafness from Eustachian obstruction.

(3) The adenotome is slipped under the soft palate, its box being pushed high up into the naso-pharyngeal vault. To effect this the shaft of the adenotome must be pressed down upon the middle line of the lower jaw.

(4) The blade is pushed home. This requires considerable force and when the adenoid growth is tough, as in adults, may require the strength of the surgeon's two hands.

It is absolutely necessary, during the pushing home of the blade, to press the box of the adenotome firmly and immovably upwards, against the vault of the naso-pharynx. If the adenotome is permitted to move or to slip, and particularly if any downward movement of curettage is made while the blade is pressed home, the result will be incomplete removal of the growth.

If removal is incomplete, one of three conditions will be found upon digital palpation: (a) the upper pole of the adenoid has escaped removal, (b) the lower pole of the adenoid has escaped removal, (c) both upper and lower poles of the adenoid have escaped removal.

These errors are remedied by a second application of the adenotome, so adjusted as to remove the fragments. It is never necessary to resort to the curette. Some authorities advise three applications of the adenotome, one to remove the central mass, and one at each side to remove the lateral masses. If the growth has been correctly adjusted by finger manipulation the whole of it will be included in the box of the instrument on its first application.

Attempts to remove lateral masses by deviation of the adenotome from the middle line may result in possible injury to the Eustachian tubes. Apart from lateral masses there are often adhesions in the fossa of Rosenmuller, but these should be broken down by the finger during the preliminary digital exploration already described.

It is important to use the largest instrument that can be pushed up into the naso-pharynx. One that will go in easily without any stretching of the soft palate is too small to engage the whole of the growth. The La Force adenotome, however large, cannot injure the Eustachian tubes, when applied in the manner described. It is a physical impossibility for the blade to cut through anything but the base of the growth. Further applications of the instrument to the side walls of the naso-pharynx are evidence only of the operator's failure to appreciate the object of the instrument, which is the complete removal of the pharyngeal tonsil, in one piece, by the one movement of pressing home the blade once only.

The Removal of Magnetic Intraocular Foreign Bodies

By F. H. VERHOEFF, M.D.

(Abstracted from *American Journal of Ophthalmology*, August, 1932, Vol. XV, p. 685)

It is a matter of common observation that flying missiles far less often strike the pupillary area than some other part of the cornea, but I have encountered few ophthalmologists who could explain this fact. The explanation, of course, is that the pupillary area is much smaller than the total remaining area of the cornea, so that the chance of its being struck is correspondingly less.

In the vast majority of cases, an intraocular foreign body is found to be magnetic even when the history seems to indicate otherwise. Usually the accident occurs when some object is being struck with a hammer, and, generally speaking, the smaller the fragment sent off, the greater its relative velocity and the greater its penetrating power. On the other hand, the smaller

the fragment, the greater the relative resistance it meets. Hence an intraocular foreign body is usually neither very large nor very minute. I have found that it is seldom more than 3 mm., or less than one-fourth mm., in its greatest dimension.

For obvious reasons, the size of the wound of entrance cannot always be relied upon as an indication of the size of an intraocular foreign body. Nor can the position of a corneal wound relative to a wound in the iris or lens be relied upon as an indication of the location of the foreign body, since, owing to some irregularity in its shape, the foreign body may swerve markedly while passing through the lens and vitreous. Many years ago an astute observer, whose name I cannot recall, made the observation that incarceration of the iris in a corneal wound was proof that there was no foreign body within the eye. I have met with few exceptions to this rule.

When there is a question of the presence of an intraocular foreign body within the eye, it is important to search for a hole in the iris. Sometimes it is impossible to recognise this by observing the surface of the iris by direct illumination, whereas it can be easily seen by throwing the light through the pupil and thus illuminating the iris from behind. If with the ophthalmoscope a non-perforating wound is seen in the fundus, it is almost certain that a foreign body is lying free in the vitreous chamber below. A small perforating wound of the sclera is sometimes invisible. In such cases an ophthalmoscopic examination often reveals more or less blood in the vitreous and thus indicates the advisability of an x-ray examination. I have seen many cases in which a wound of the cornea had been regarded as non-perforating and the presence of an intraocular foreign body overlooked. In some of these cases siderosis of the iris and lens capsule had developed while the patient was under observation. So far as I know, I have never made this mistake but possibly some of my colleagues could testify otherwise. It would seem to be unjustifiable to have an x-ray examination made in every case of apparent trivial injury to the eye, but if this were done fewer serious mistakes would be made. On the other hand, I have seen cases in which an intraocular foreign body had been carefully located by x-ray examination, when it could be plainly seen with the ophthalmoscope, and I have removed minute intraocular foreign bodies from eyes in cases in which x-ray examinations by experts had failed to reveal them. A localization of a foreign body close behind the globe should not be accepted without confirmation by a magnet test, and if possible, by ophthalmoscopic examination.

I have seen a few cases of xenogenous siderosis in which the patients were unaware that they had ever sustained injuries to their eyes. In my experience, after removal of a foreign body from an eye with siderosis, the vision is apt to continue to deteriorate to greater or less extent, owing no doubt, to iron remaining in the fluids of the eye.

Exact determination of the location of a foreign body in the posterior part of the eye is only exceptionally needed, since the same procedure for its removal is first tried no matter what its position may be. If the large magnet placed in front of the cornea fails to bring the foreign body forward, then a fairly exact knowledge of its size and position becomes important. Attempts to dislodge a foreign body by means of the magnet should not be abandoned until after they have been made on at least three successive days, for by repeated attempts the foreign body may be gradually loosened so that it may finally come away.

When an eye containing a foreign body is hopelessly infected no attempt, of course, should be made to remove the latter. A small hypopion, however, is not a contraindication to operation. In a number of cases after removal of a foreign body I have seen a hypopion one-half millimetre high rapidly disappear and normal vision return. Within recent years in all such cases of intraocular infection I have given daily subcutaneous injections of 20,000 units of diphtheria antitoxin. These

have been continued for a week unless in the meantime the infection has subsided or has become obviously hopeless.

For many years I have accepted the teaching of Haab that the safest way to remove a magnetic foreign body from within the eye is through the anterior chamber. Those who advocate removing it through a posterior scleral incision are, I believe, influenced chiefly by the facts that this method is simpler and does not require so powerful a magnet. The danger of subsequent separation of the retina is undoubtedly far greater after a scleral incision and for this reason the posterior route, in my opinion, should never be used unless it is found impossible to bring the foreign body from behind the lens, or there is a large open wound of the sclera.

I have made it a rule never to remove a foreign body through its corneal wound of entrance unless it is already engaged therein, because reopening a wound increases the scar formation and also increases the danger of infection. In a few cases I have made an exception to this rule when the wound was large and gaping, especially if it was near the limbus. In such cases the foreign body is, of course, large and the lens injured. A small magnet should at first be tried with the patient reclining, and the tip applied directly to the wound. By using a large magnet held at a distance, I have seen operators pull out the entire iris along with the foreign body. After the foreign body has been removed, as much lens matter as possible should be expressed through the wound. If the iris has now prolapsed an attempt should be made to replace it. If this fails, the prolapsed portion should be excised. A conjunctival flap over the wound is seldom indicated.

Before attempting to remove a foreign body from the vitreous chamber *via* the anterior chamber, it is important to dilate the pupil to the greatest possible extent. The patient is seated on a stool in such a position that the injured eye can be brought against the tip of the large magnet. He is then leaned backward until his eye is about two feet from it. The current is then turned on and the patient gradually brought forward until the magnet tip touches the centre of the cornea. If the foreign body has not appeared or the iris bulged forward, the current is repeatedly turned on and off. If this fails, the opposite pole of the magnet is tried in the same way and if this fails the magnet tip is applied at other parts of the cornea and at the limbus. This failing, an attempt should be made to bring the foreign body forward in relays. The eye is turned to one side if necessary, and the tip of the magnet applied to the sclera, first at a point close to the foreign body, and then over the pars plana of the ciliary body. If pain is now elicited, it is certain that the foreign body has come forward, and the tip of the magnet should again be placed opposite the centre of the cornea. As a result of one or another of these manoeuvres in many cases the foreign body will come around the lens and from behind the iris into the anterior chamber, but not infrequently it is held back by the iris. When this happens I employ a procedure that I described some years ago. I place the tip of the magnet at the limbus just in front of the level of the iris and just above an imaginary line which runs through the foreign body and is tangential to the pupillary margin. When the current is turned on, the foreign body will usually slide along the margin of the pupil into the anterior chamber. If it has become so firmly stuck in the iris that it will not come away, it may often be freed by applying the tip of the magnet at the limbus at a point near the foreign body; and then at the point just described. I have observed that in such cases many operators place the tip of the magnet diametrically opposite the foreign body. Owing to the resistance offered by the sphincter this procedure generally causes the foreign body to become still more firmly entangled in the iris and it may even cause iridodialysis.

After the foreign body is within the anterior chamber it of course sinks to the bottom of the latter. Until

recently I have always made the incision for its removal above, for the reasons that if post-operative prolapse of the iris should occur it would be preferable to have it do so above, and that it is less difficult to make a keratome incision here than below. I now believe, however, that these considerations are more than offset by the advantages of making the incision below, namely that the foreign body is below and that the patient naturally tends to look up during the operation. As a matter of fact, the danger of post-operative prolapse is negligible, owing to the small size of the incision necessary.

In making the incision, whether above or below, the point of the keratome should be entered as far back from the limbus as possible without danger to the lens or iris. If the incision is made too far forward, the shelf of corneosclera may prevent the foreign body from entering the wound. If the keratome is sharp, the incision can generally be made without obliterating the anterior chamber. If the latter is obliterated, it should be reformed by forcing salt solution into it with an irrigator. Otherwise, if the incision has been made above, the lens or cornea may be scratched by the foreign body. For a removal of the foreign body from the anterior chamber I have found a permanent magnet most convenient. It is important to draw the foreign body to the incision before inserting the tip of the magnet as otherwise the anterior chamber may be evacuated before the foreign body can reach the incision.

When the patient was a 'bad actor' and the lens clear I have employed either of two procedures. One consisted in having an assistant apply a small magnet to the metal handle of the keratome while I was making the incision. This kept the foreign body in the vicinity of the wound where it remained in case the anterior chamber was evacuated. The other procedure consisted of placing pillows under the shoulders of the patient so that his head was in such position that the plane of the iris was parallel with the floor. The foreign body was then drawn to the upper limbus where it remained when the incision was made. I now believe, however, that it is better to dispense with both of these procedures by making the incision below.

In exceptional cases a foreign body, after coming forward, becomes so firmly stuck in the iris that it is impossible to bring it into the anterior chamber. In some of these cases I have made the incision at the limbus near the foreign body, applied the magnet to the wound until a knuckle of iris prolapsed with the foreign body behind it. I then removed the magnet and snipped a small hole in the iris with scissors, and then again applied the magnet. In a few cases it was necessary to complete the removal of the foreign body by means of forceps in order to avoid too great traction on the iris. In others of these cases I have made a large incision at the limbus near the foreign body, pulled out the iris with iris forceps as if to do an iridectomy, and then removed the foreign body with the magnet. An objection to this method is that the iris is so greatly bruised that it becomes adherent to the lens. It is therefore important to replace it in normal position as otherwise the pupil may remain considerably distorted.

If the lens has been so severely injured that it would undoubtedly soon prevent any useful vision in the injured eye I remove it at the same time as I remove the foreign body. I make a large incision with the keratome, remove the foreign body with the magnet, then remove a large piece of the anterior capsule with the toothed capsule forceps, and then by expression and irrigation remove as much lens matter as possible. In this way the patient is spared a second serious operation and his total convalescent period is considerably shortened. On the other hand, if I think the lens may remain fairly clear for a considerable period of time, I delay its removal until it has become completely cataractous.

When a foreign body has lodged within the lens, both the foreign body and the lens should always be removed at the same operation. The operation, however, should be delayed until the resulting cataract prevents useful vision, unless siderosis of the lens capsule becomes evident before this. In a case in which a foreign body is embedded in the iris and has probably injured the lens, it would seem best to wait for a week or two before removing it, and to refrain from using a mydriatic. The delay may permit the wound in the lens capsule to become closed and thus prevent the formation of a progressive cataract.

A few cases present themselves in which it is not possible to use the anterior route. These include cases in which the foreign body is very large, or in which it is too small or too slightly magnetic to be attracted around the lens, and cases in which the foreign body cannot be dislodged by the magnet. When the foreign body is large, it generally has produced so much damage that the vision of the eye is destroyed sooner or later in any case. If the wound of entrance is through the sclera, and is still open, I remove the foreign body through it, if it is small and closed, I make an incision elsewhere as described below.

Many years ago I pointed out that theoretically the safest place to incise the globe posteriorly is through the pars plana of the ciliary body. This is anterior to the pars optica retinae, and even anterior to the vitreous, so that, for obvious reasons, there should be much less danger of post-operative retinal separation if a foreign body is removed through an incision here than if it is removed through an incision farther back. I have, however, seen separation of the retina follow removal of a foreign body through such an incision. In some cases this was evidently due to traction of the vitreous upon the retina at the site of the foreign body, and would, therefore, have occurred even if the anterior route had been used. In other cases it presumably was due to traction exerted upon the retina by vitreous which had been dragged into the operative wound.

Within the past few years, I have, I believe, made the operation still safer by incising the sclera gradually. Instead of plunging a cataract knife directly through the ocular wall into the vitreous as is usually done, I employ a large knife needle, the point of which has been filed off. A Post knife needle or a very large Knapp knife needle will serve. After dissecting up a conjunctival flap and inserting a suture ready to tie, with repeated sweeps of the cutting edge of the knife needle an incision is made in the sclera, parallel to the ora serrata at a distance of about 5 mm. from the limbus. Great care is taken not to incise the ciliary body. After the sclera is partly cut through, one edge of the incision is grasped with fixation forceps and the incision into the perichoroidal space completed by forcing the blunt point of the knife beneath the remaining scleral fibres and then cutting outward. The large hand magnet applied to the wound will now cause the ciliary body to bulge. If the foreign body is small and sharp it may at once come out through the ciliary body. If it does not, a small cut is made in the ciliary body and the magnet again tried. If the foreign body still fails to come out, the cut is enlarged to the extent necessary as found by repeated trials.

In rare cases the foreign body is so firmly embedded or encysted in the posterior ocular wall that it cannot be dislodged with the magnet. If it is sufficiently far forward, it may sometimes be removed by incising the sclera directly over it. The sclera should first be carefully incised, then a small incision made in the choroid, and the large hand magnet applied. If the foreign body presents itself but is held back by the scar tissue in which it is encysted, it may be grasped by forceps and freed by snips of scissors. If it does not present itself, a bent magnet tip should be inserted through the incision and carefully moved around in various directions. If a foreign body is encysted far back in the fundus, it is best not to attempt to remove it until

it begins to cause deterioration of the vision. In some cases it becomes so thoroughly encysted that good vision is maintained for many years. If it becomes advisable, an attempt to dislodge it may be made by passing a knife needle through the sclera just anterior to the ora serrata and picking at the foreign body while it is observed through an ophthalmoscope. This is, of course, a difficult procedure and must be carried out quickly, as the corneal epithelium rapidly becomes cloudy and obscures the view.

In a case in which the foreign body had penetrated the fundus about 6 mm. above the macula, and was partly within and partly outside the eye, I made an incision through the upper lid along the outer orbital margin, exposed the foreign body to view, and removed it with forceps. Excellent vision was maintained after the operation.

Thallium Acetate: Its Toxicity and Depilatory Action

By HERMAN GOODMAN, M.D.

(Abstracted from the *New York State Journal of Medicine*, Vol. XXXII, November 15, 1932, p. 1307)

Clinical use and toxic effects.—In 1898 Combemale used 10 to 20 milligrammes for night sweats in patients with tuberculosis. He noticed that the loss of hair was rapid and complete. The next year Richet associated chronic poisoning with thallium and muscular atrophy.

Early clinical experiment.—A physician 37 years of age who took thallium for experimental purposes. He took one half to one gram every second day for three or four doses and then after two months he took several doses more. Nothing happened after the first experiment, but three or four days after the second, he noticed numbness in his fingers and toes and was taken to the hospital where his case was diagnosed as multiple neuritis.

Mechanism of action of thallium.—The remarkable action of thallium acetate in producing alopecia is so far as is known shared by no other substance. The exact mechanism of its depilatory action is not absolutely known, but certain established facts appear to show that this action is upon the sympathetic nervous supply of the follicles and not directly on the follicle or hair bulb itself. Endocrine glands are clearly concerned in the action of the drug. The post-mortem examination of the animals which had undergone prolonged thallium feeds revealed in all cases changes of an atrophic nature in the suprarenal glands, the thyroid and testes.

Thallium alopecia is directly due to the action of the salt on the hair-forming process. A series of histologic examinations of the scalp of patients treated with thallium show evidence of epithelial degeneration of the hair follicles and sclerosis of the connective tissue.

Animal experimentation.—Rat poison—zelio paste—which is 2.8 per cent. thallium, and zelio corn which is 2.1 per cent. thallium was mixed with the food; ill effects were noticed within from 16 hours to 4 weeks. Two weeks were needed for the loss of hair or alopecia. Examination of the rats and other animals showed degenerative changes in the central and peripheral nervous systems. There was a diffuse ganglionic disease. There was no damage done to any portion of the central nervous system. Schneider thinks that thallium acetate is very toxic. His opinion is that it is necessary strictly to limit its use. He reports that this thallium rat poison had been used by suicides and criminals with intent to kill.

Rat poison in the form of thallium sulphate was tested on sheep. The dose was 25 mg. per kilo of weight. The animals died on the 8th day. Doses of 10 mg. per kilo of weight were so small that the sheep survived but a noticeable slipping of the wool took place from the 13th day.

The symptomatology of thallium poisoning among the sheep included clamping of the teeth, loss of

appetite, general dejection, digestive disorders, muscular cramps in the hind legs, and coma. Death was due to respiratory failure.

Epilating action of thallium.—Drummond stressed the point of some biological and also practical interest in the fact that epilation following thallium leaves a narrow strip of hair across the forehead (the 'old Man's fringe') unaffected. It has been proved according to Drummond that this hair shows a greater resistance to external and internal irritation than other hair growths. The eyebrows likewise are unaffected. He asserts that thallium is highly toxic to adults and should not be given to them.

Feldon reviewed the statements and warnings regarding the intoxication from the use of thallium acetate in the treatment of ringworm of the scalp of children. He noted the peculiar fact that thallium cannot be used in the same dosage after the development of puberty without greater danger than in children. There is a marked increase in the toxicity which is probably due to the changed function of the endocrine-sympathetic system after maturity. He gives a report of two children, one a girl aged 15 who was completely infantile physically, size of child of 3 and only 35 lbs. in weight. Second child was a boy, a cretin, also infantile, age 19, but of the height of a child of 5 or 6 years. These two children showed only a slight epilatory effect which was insufficient to remove all of the infected hairs. This was undoubtedly due to the marked disproportion between age and body weight. The development of the endocrine organs possibly is parallel to the age and not to the body weight and if so the dosage made according to body weight does not correspond to the size of the endocrine organs.

Toxic action of thallium.—Several cases occurred of poisoning with suicidal intent from thallium in a rat poison sold freely in Vienna without a poison label. Characteristic symptoms in these cases consisted of pain in the joints, swelling of the feet and legs, colic, vomiting, sleeplessness, mental confusion, and a striking loss of hair from the head and body about three weeks after the administration of the poison. Too rapid administrations of thallium for therapeutic purposes has also been attended by toxic manifestations. The authors stated that a period of two to three months should elapse between the first and second administration of thallium. They write that it is possible to demonstrate thallium in the blood and urine within four weeks after the administration of a large dose. They mention that thallium is used in industry in the making of colours, window glass, and luminous paints, and that poisoning is possible from occupational contacts.

An attempted suicide spread half a tube of zelio paste on bread and swallowed it. The patient became ill two days later with pain and weakness in the lower extremities, albuminuria, loss of hair on the 11th day. She was ill for several months, suffering from peripheral neuritis, loss of appetite, pain in the chest, emaciation, depression, and amenorrhœa.

A number of cases of industrial thallium poisoning occurred in workers in a factory for the recovery of thallium. They had inhaled a powder (dust) of metallic thallium that is composed of thallium oxide and thallium sulphate. Besides alopecia, signs of poisoning manifested themselves in fatigue, anorexia, pains in the joints and lower extremities, albuminuria in nearly all cases, and a definite lymphocytosis of over 40 per cent. In one case there occurred after a month, heart burn and redness of the hair. Four months after beginning of regular work with thallium one patient showed a diminution of vision that progressed rapidly.

Cosmetic depilation with thallium.—Sabouraud as far back as 1897 suggested the use of thallium acetate as a depilatory. In 1912 he advocated the use of thallium acetate in 1 per cent. concentration once a day in a very small quantity and over a very small surface.

Sabouraud used thallium acetate in his service at the Hospital St. Louis to bring about a complete removal of the hair in children affected with tinea.

Sabouraud reported that thallium acetate by ingestion is capable of causing loss of hair in 15 days. It is not a harmless remedy and is to be used only under proper direction. He has shown that a paste of thallium acetate of 1 or 2 per cent. concentration applied every night to the lip and chin can within 6 or 8 months cause a reduction of the moustache or a commencing beard. The medicament should be used with care for one sees a number of cases of intoxication. It is essential to write the particulars of the dosage on the prescription. These are: Each evening treat only a small area of the total area of excess hair to be treated. The ointment must be applied by massage and the hands must be washed immediately thereafter with soap. The results will then be attended with little danger. All the accidents observed were among young girls who used the medicament in three times the dose advised. Grave toxic effects have been seen as temporary loss of all hair, temporary paralysis of the extremities, and nerve toxicity of several weeks' duration. Sabouraud was convinced that only those patients who did not follow his advice were the subjects of these accidents.

A 10 per cent. thallium cream has been used in hypertrichosis and sycosis, but an alopecia of the scalp frequently resulted with or without epilation of the area treated. A 10 per cent. cream was considered too toxic. Ionization has been utilized with a 2 per cent. solution of thallium acetate. It has been reported partially successful in hypertrichosis.

A commercial thallium depilatory.—A patient was reported to have used cream on the upper lip and under the chin. Two weeks after use of the cream she noticed pain in the chest, cramps, nausea, vomiting, and constipation; papuloid purpuric spots; hair of scalp was loose and easily pulled out; the eyebrows and eyelashes were not involved, but the scalp was completely bald except around the ears.

The formula for epilating cream as used by Sabouraud was—

Acetate of thallium	0.3
Zinc oxide	2.5
Vaseline	20.0
Lanoline			
Rose water	55 5.0

Further clinical reports.—A case was reported of thallium poisoning from prolonged use of depilatory cream. Patient had used the cream nightly for the preceding 5 months beginning its use 2 weeks before appearance of the first symptoms. A quantity sufficient only to cover the upper lip and chin had been used on each occasion. At each application the cream was well rubbed in. At the time of examination hair was distributed normally over the body with exception of the face where the growth was more profuse than is normal, and this hair was firmly imbedded.

Hair-growing properties of thallium.—The stimulating effect of small doses of thallium acetate on the rate of growth of hair in the rat has been noted. Single doses of 0.004 and 0.006 grams of thallium acetate per kilo body weight dissolved in distilled water injected intraperitoneally into white rats produced 18 per cent. increase in the rate of hair growth. Doses of 0.002 grams per kilo weight were too small to produce any effect on the rate of hair growth.

Absorption of thallium.—Dixon was definite that the symptoms of toxicity due to thallium depend on absorption. Thallium rubbed into the skin has no local action. Thallium is readily absorbed into the skin with alcohol or oil. It causes alopecia only after absorption. The effect is mainly on the autonomic motor system which is rendered more sensitive. However, this is more marked on the sympathetic portion, so that electric stimulation of the nerves produces an exaggerated response, even though the stimuli are below the normal response level.

Pathology of thallium toxicity.—1. The thallium preparations, by their influence on the vegetative nervous system, produce a series of changes on the latter, which in their turn act on the appendages of the skin, particularly on the hairs, causing a whole line of plethoric disturbances to the vessels of the hair bulbs, now in the shape of phenomena of an inflammatory character, with infiltration of round-cells; now again as foci of agglomerated cells, in the shape of furuncles.

2. Like all other salts of the heavy metals, such as mercury, bismuth and lead, thallium can produce a great many serious disturbances in the organism. These disturbances are as follows:

(a) In the skin, besides falling of the hair, folliculitis and a toxic eruption similar to the ones produced by mercury or bismuth, and of a hæmorrhagic character as petechiæ and ecchymoses.

(b) In the mucous membrane of the mouth, besides gingivitis, glossitis and stomatitis—even in its ulcerative form—the phenomena of an angina thallii. One also encounters cases of herpetic eruption, rhagades and sanguineous spots on the lips; and it should be noted that thallium can cause diarrhœas and sharp pains in the stomach.

(c) The mucous linings of the stomach and intestines show a picture of either stippled or completely fused hæmorrhages, besides one of either desquamative or ulcerative colitis.

(d) In the liver, we notice, besides hæmorrhages, thallium necroses and nephritis.

(e) In the liver and spleen, the phenomena are mostly of a vascular character. Besides rapid palpitations of the heart, we sometimes find paracardiac pains, which must probably be explained as due to influences from the vegetative nervous system.

(f) Acting on the vegetative nervous system, the thallium preparations can thus, through the latter, affect also the other branches of the nervous system, thereby producing those phenomena of quickly passing, epileptiform psychosis termed chorea. They can also act directly, and produce such phenomena as, for instance, thallium polyneuritis, disturbances of the blood vessels, including the periphæric blood vessels of the brain, and cerebral hæmorrhages.

(g) At the same time as the polyneuritic phenomena, one notices pains in the articulations, astragalgiæ, accompanied by swelling, tenderness and crackings.

(h) The disturbances thus described can be accompanied by pyrexia, and can cause the patient to become greatly emaciated and very weak, by changing the metabolism in the direction of a disaggregation of the blood-corpuscles already from the first dose of the thallium. They can also express themselves by interfering with the process of assimilation of the ingested food, a complication occurring especially in connection with serious disturbances in the intestine.

Retrobulbar neuritis.—Loss of sight as a result of thallium poisoning had been observed. Retrobulbar neuritis due to thallium poisoning from depilatory cream occurred in three patients. The cause of the toxic optic neuritides was not suspected at first. Each of the patients reported gave a history of the use of a proprietary depilatory cream.

The three patients were admitted to the neuro-surgical clinic as 'intracranial tumour suspects', and were found to have an advancing retrobulbar neuritis. Their failing vision was checked, and improved by discontinuing the employment of the thallium depilatory.

Therapeutic thallium for ringworm.—A number of children were examined at one time or another who had received the thallium acetate properly weighed for epilation of the scalp preliminary to antiseptic treatment for tinea capitis. One child was very ill with symptoms of intestinal upset, articular inflammation, marked pains in the chest, inability to hold food, loss of weight, and general debility. This patient required hospitalization.

The epilation of the scalp following thallium acetate was observed. The complete epilation of the pre-puberty group, and the partial epilation of the post-puberty group led me to frame the concept of nerve baldness. It appeared that thallium acetate probably acted through the sympathetic nervous system. The loss of hair was more nearly complete prior to puberty than after puberty was established. The control of the scalp hair of the entire scalp was under the sympathetic until puberty, and that the central nervous system then had a share. The recorded observation of Celsus made almost 2,000 years ago that persons with alopecia areata of the ophioid type (periphery of the scalp) offered a poor prognosis compared to those with loss of hair in the centre of the scalp was considered in this concept. Then, too, it is known that the borders of the scalp hair are more resistant to dye. Further, when a man loses his hair from the centre of the scalp in the pattern of the calvities Hippocratica, the hair at the periphery grows more rapidly so that the bald headed person must have less and less hair cut more and more often.

One of my assistants began the use of thallium acetate by ionization for the treatment of excess hair of the chin and moustache region. He did not finish the experiment because of the reports of toxic action by this method of administering the drug.

Animal experiments.—The reports that pilocarpine hydrochloride had the effect of growing hair when injected locally, given by mouth, or used as a scalp wash seemed to indicate that the action on the sympathetic nervous system of the pilocarpine and the thallium might be antagonistic. With this in view, a series of experiments were made:

Three guinea-pigs of about the same weight and age were selected. Pig one was given 8 milligrammes per kilo of weight of thallium acetate dissolved in water forcibly by mouth. Pig two received 8 milligrammes of thallium acetate and in addition one-twelfth of a grain of pilocarpine hydrochloride by mouth. Pig three received one-twelfth of a grain of pilocarpine hydrochloride alone. From theoretical considerations, pig one should have succumbed; pig two should have survived; and pig three should have been unaffected. Strange as it may seem, this was what actually occurred. Pig one died within eight hours after oral administration, and the other two pigs lived. The post-mortem examination was very brief—abdominal section. It was noted that the stomach was markedly enlarged with definite constrictions at the two orifices—the œsophageal and pyloric. These constrictions were so definite that removal of the stomach by section resulted in the removal of a stomach sac which did not leak any contents at either aperture. The stomach was opened, found to contain a large quantity of yellowish fluid. The mucosa was thinned.

The oral administration did not seem to be certain. The next three guinea-pigs were given the drugs in the same dosage by intraperitoneal injection. The pig which received thallium acetate alone died within the eight-hour period. The other pigs survived. The post-mortems were more complete—the brain case was opened, and the softening of the cerebral tissue noted; the chambers of the eye were engorged; the heart muscle was congested with pronounced hyperæmia; the lungs showed dilatation of the wall, the blood vessels, and extravasation of blood into the œdematous lung tissue; the intestinal walls showed areas of denuded mucosa, and extravasation of blood into the coats; the liver, spleen and kidney showed the same picture: œdema, widening of the blood vessels; and extravasation into the tissue of blood elements. The pathologic pictures were monotonous—and similar to those found by others.

The surprising repetition of the action of the pilocarpine hydrochloride in preventing the action of the thallium acetate immediately must be commented upon, but further experiments along the same lines have not given the same results. In the most recent experiments, the pigs receiving thallium acetate and pilocarpine hydrochloride died. The pathological findings were the same for both sets of pigs.

The main purpose of the experiments was to attempt to find if there was any antagonistic action between the two drugs. Our final conclusion is that none was really demonstrated by our work.

The pigs died too soon after the administration of the lethal dose of thallium acetate to expect any action on the hair. There was no effect noted. It is our opinion, that experimentation on the rate of growth of hair in the rodents is very difficult of control. The normal rate of regrowth after any procedure is very rapid. Local application of thallium paste to the skin of these animals must be guarded as it is impossible to prevent the animal from licking the paste and getting it into the system by this means.

SUMMARY

Thallium acetate and other salts of thallium have been recognized as toxic to man and animals from the time of the discovery of the element. Its use in night sweats disclosed the epilating action. Sabouraud attempted to make use of this action in the cosmetic removal of unwanted hair but found many untoward reactions and has guarded his prescriptions for this purpose. Many attempts to explain the epilating action of thallium have been made, but there is no agreement as to the mode of action. It seems accepted that the metal has an effect on the sympathetic nervous system, although a local action on the hair-forming process is claimed. The toxic action of thallium salts on animals has been used in poison potions for undesirable animals. Rat poison containing thallium has been used in criminal attempts to kill and by those desiring to commit suicide.

Within the past two decades, there has been a revival of the therapeutic action of epilation through thallium. Thousands of children have received the drug for the preliminary epilation of the scalp hairs to afford treatment of infestation with tinea organisms. Toxic effects due to the drug in proper dosage, and deaths from the inadvertent use of large doses because of poor mathematics or misunderstanding of orders have been reported. It is true that thallium is falling into disfavour, that is, in so far as its use as therapeutic epilatory is concerned for scalp hairs.

On the other hand, commercially minded concerns have taken advantage of the work of Sabouraud, and have placed before the public various thallium creams for the epilation of unwanted hair of the face and arms. Women are tremendously sensitive in our day and age to any hairiness. The sales of one American product which promised miracles at a high price were very large. Many women used this paste. Throughout the country, undiagnosed instances of thallium intoxication were treated for many conditions, but the rôle of thallium was soon uncovered. The physicians throughout the country have reported such unmasked thallium acetate poisoning.

My clinical experience and what few experiments I have done follow that of others in this field: thallium acetate as a depilatory does offer the opportunity of toxic action on persons using it whether for cosmetic effect (unwanted hair) or therapeutic action preliminary to antiseptic treatment of infested follicles with ring-worm or favus. Pilocarpine hydrochloride does not prevent the lethal action of a lethal dose of thallium acetate administered intraperitoneally into guinea-pigs.

It is our opinion, also, that many of the toxic results obtained from the external applications of thallium paste for the epilation of hairs of the upper lip or chin follow inadvertent oral administration. The application of the paste to the upper lip can easily lead to absorption by mouth. The very intimate contact of the upper lip and food or drink would permit of such absorption. The intermediate pillow case could also lead to such oral administration. The thallium acetate left on the massage fingers could easily be transferred to food eaten from the hand. Sabouraud recognizes this for he advises careful washing of the hands after the application is made.

The Aschheim-Zondek and other Laboratory Tests for Pregnancy

By G. V. RUDD, M.Sc.

and

W. WILSON INGRAM, M.C., M.D.

(Abstracted from the *Medical Journal of Australia*, Vol. II, No. 21, November 19, 1932, p. 629)

THE researches of Aschheim and Zondek led them to conclude that the anterior lobe of the pituitary gland secretes two hormones which are intimately related to the functions of the ovaries. These two hormones, which they refer to collectively as prol-an, or individually as prol-an A and prol-an B, they regard as the stimuli of ovarian activity. Prol-an A induces maturation of the Graafian follicles; in the *liquor folliculi* of the mature follicles the presence of the hormone, variously called the female sex hormone, œstrin or theelin, has been demonstrated. Prol-an B is the term used to designate that factor in prol-an which effects luteinization of the follicles; and the *corpus luteum* produces the hormone progesterin, which causes the changes in the uterine mucosa before gestation occurs. Other investigators have failed to effect a separation of prol-an A and prol-an B, and incline to the belief that there is no real distinction between them. Collip has found in extracts from the placenta indications of three hormones which he believed to be distinct from those already mentioned. He has now found, however, that the one which he named emmenin is identical with œstrin. The question of the hormonal control of the reproductive cycle becomes obscure in the presence of all these factors. One clear fact that emerges is that conception is rapidly followed by a great increase in the quantities of prol-an in the blood and by its excretion in the urine. This is demonstrated by the injection of these fluids into immature female mice, a procedure which is followed by rapid maturation of the ovaries and precocious puberty. It is upon this fact that the Aschheim-Zondek pregnancy test is based. The technique of this test has previously been described in this journal and will be referred to only briefly here. Immature female mice receive six subcutaneous injections of the urine to be tested over a period of two days. One hundred hours after the first injection the animals are killed and their ovaries examined macroscopically for the presence of hæmorrhagic follicles and corpora lutea. The presence of these is diagnostic of pregnancy, whilst the finding of infantile ovaries rules out the possibility of pregnancy. The German authors claim an accuracy of nearly 99 per cent. in their results, which appear to be fully confirmed by workers in various parts of the world.

Many attempts have been made to reduce the time necessary for the completion of the test. Friedman observed that the intravenous injection of the urine of a pregnant woman into rabbits provoked ovulation. Since ovulation occurs in the rabbit only after coitus, Friedman's observation may be used as the basis of a test for pregnancy. Thus Reinhart and Scott developed a technique by which non-pregnant rabbits were isolated for a week and then injected with five to fifteen cubic centimetres of the urine of the patient in whom pregnancy was to be diagnosed. Laparotomy was performed on the animal after twenty-four hours. A positive indication of pregnancy was given by evidence of ovulation, as shown by the presence of hæmorrhagic follicles in the ovaries. If there was no evidence of ovulation and mature Graafian follicles were present, a further injection of urine was given and laparotomy was again performed twenty-four to thirty-six hours later. The non-appearance of hæmorrhagic follicles at this operation was considered a 'negative' reaction to the pregnancy test. From a discussion of the rabbit pregnancy test by White, Severance and others, it appeared that in order to attain the maximum accuracy with the test more than one intravenous injection was necessary, even in carefully selected animals. Also, the

animal must be examined at least forty-eight hours after the first injection to exclude false 'negative' reactions to the test although, of course, earlier indications of a positive reaction may be obtained by laparotomy.

Zondek has attempted to reduce the time taken by the Aschheim-Zondek test by alcohol fractionation of the urine, a procedure by which he concentrates the active principle six times. He examined the ovaries of the mice fifty-one to fifty-seven hours after the first injection. His conclusion is that a positive reaction is diagnostic of pregnancy, but that absence of reaction does not exclude pregnancy. He therefore always controls these results by carrying out the test with the ordinary technique. Ebersson and Silverberg also prepared by alcohol fractionation a concentrate of the active principle of the urine of pregnancy which effected maturation of the ovaries of immature rats. They performed post-mortem examinations of the animals forty-eight hours or longer after the first injection, but in an unspecified number of cases were compelled to resort to microscopic examination of the ovaries in order to reach a conclusion from the test.

Clinical application of the Aschheim-Zondek test.—The Aschheim-Zondek test has been used in this hospital as a diagnostic aid in a variety of conditions. In this connection 93 cases have been investigated. In addition, fifty-two tests were carried out as controls on the urine of patients known with certainty to be either pregnant or non-pregnant. Thus, in all, 145 tests were carried out, and in every case the result was correct. This remarkable accuracy leads one to place great confidence in the test.

Aschheim has pointed out that a positive reaction to the test occurs as long as the foetus lives and the chorion is in living contact with the mother's circulation. Within a few days of the death of the foetus the test fails to produce a reaction. In four cases in which a provisional diagnosis of dead foetus had been made, the two positive reactions were obtained from urine passed by the patient whilst the foetus was still alive or had just died. The specimens of urine failing to give reactions were passed by the patient a considerable time after the death of the foetus.

A quicker test for pregnancy.—The Aschheim-Zondek test has the disadvantage that the result is not available until one hundred hours after the commencement of the test. With the rabbit pregnancy test the result may be read forty-eight hours or less after the test is undertaken. Here the effect of the urine injections is merely to provoke ovulation by the already mature Graafian follicles, but in the mouse maturation of the follicles must first be effected before ovulation can occur. It was therefore believed that more rapid tests would be possible by means of mice if they were used at an age nearer to puberty than had been customary. With this end in view, sections of the ovaries of a large number of mice were examined. It was found that there was no evidence of luteinization of maturing follicles before the age of thirty-six days, and even at this age it was very rarely encountered. Macroscopically, all ovaries taken from mice up to this age appeared normally infantile. It seems permissible, then, to use animals of such an age that they shall be not older than, say, thirty-four days at the end of the test. With them, one would expect a more rapid response to the injection of the urine of pregnancy than with considerably younger animals.

Dickens has shown that prolan is precipitated from urine by concentrations of alcohol above 75 per cent. This observation has been used in concentrating the active principle in the urine during pregnancy in the following manner.

The urine, slightly acid to litmus, is mixed with three volumes of absolute alcohol and allowed to stand for thirty minutes. The mixture is centrifuged and the supernatant fluid is poured off. The precipitate is taken up in a small volume of water and the mixture is again centrifuged. The aqueous extract is found to be highly

active. Usually it is convenient to take fifty to sixty cubic centimetres of urine and 150 to 180 cubic centimetres of absolute alcohol. The precipitate may be spun down in a hundred cubic centimetre centrifuge tube in three spins, the supernatant fluid being discarded each time. After the final spin the supernatant fluid is decanted off and the tube drained for a few minutes or if the precipitate is bulky, the tube is placed in a water bath at 40°C. and exhausted for a few minutes in order to remove most of the alcohol. The precipitate is taken up with 1.5 cubic centimetres of distilled water and transferred to a 10 cubic centimetre centrifuge tube. The large centrifuge tube is washed out with three quantities of 0.7 cubic centimetre of distilled water and the washings are added to the 10 cubic centimetre centrifuge tube. After thorough mixing the insoluble portion is centrifuged out. The concentration effected by the procedure is about 15 to 1. In order that the final solution may contain as much prolan as possible, specimens of urine which are not too dilute are used. Usually the early morning specimen serves the purpose well.

Preliminary tests with the concentrates prepared in this manner showed that two injections of 0.3 to 0.4 cubic centimetre were sufficient to produce hæmorrhagic follicles in the ovaries of immature mice. Finally, the following technique was evolved and applied to a series of tests. The preparation of the concentrate from urine was commenced at 9 A.M. and was completed at 10-30 A.M. Four mice, twenty-eight to thirty days old, received two injections of 0.3 to 0.4 cubic centimetre at an interval of six hours. Fifty-five hours after the first injection, that is, at 5-30 P.M. on the third day, the ovaries of two of the mice were examined. If hæmorrhagic follicles were not seen, the remaining mice were examined early in the morning of the fourth day, that is, about seventy hours after the first injection. The finding of one hæmorrhagic follicle constitutes a positive reaction. In the absence of hæmorrhagic follicles the result of the test is 'negative'.

Tests were done in this manner with sixty-five specimens of the urine of pregnancy. All but six reacted positively at 55 hours. Of the six, five reacted positively at 68 to 70 hours. The one which failed to give a positive reaction either at 55 or 70 hours was a very dilute specimen of urine passed during the afternoon and was almost colourless. This single failure of the technique serves to stress the importance of using a well-coloured early-morning specimen of urine for the test. When this is done, the result of the test, if positive, is available in the great majority of cases in 55 hours, and, if no reaction occurs, in 70 hours. It is not suggested that this more rapid test should supplant the Aschheim-Zondek test. It is, however, a reliable test to use in those cases in which a quicker result is required.

The rabbit pregnancy test.—It has been suggested that it is a matter of greater difficulty to breed a sufficient number of mice for pregnancy tests than it is to use rabbits which are examined once or twice by laparotomy and used again when they have recovered from the operations. A more real advantage of the rabbit pregnancy test is that the result is available much earlier than in tests in which immature mice or rats are used.

In order to become acquainted with the rabbit pregnancy test, fourteen rabbits were used. They were segregated for some weeks to insure that they were non-pregnant, and then received two intravenous injections of ten cubic centimetres of urine at an interval of six hours. Forty-five hours after the first injection, the animals were killed and their ovaries were examined. The ten which had been injected with the urine of pregnancy all had hæmorrhagic follicles in the ovaries. The remaining four, which received injections of urine from non-pregnant women, had no hæmorrhagic follicles. Thus in this small series of fourteen tests, all the rabbits gave an accurate result. In those instances in which the test is urgent, the rabbits' ovaries could be examined

in twenty-four hours and a positive result would then end the test. As previously mentioned, however, the conclusion of White, Severance and others is that an animal showing no reaction at twenty-four hours must always be re-examined at forty-eight hours if 'false negative' reactions are to be excluded.

SUMMARY

(1) In 145 cases in which the Aschheim-Zondek test was used, the results were correct in every instance.

(2) A more rapid pregnancy test, based upon the Aschheim-Zondek technique, is proposed. The time taken by the test is 55 to 70 hours.

(3) Reference is made to a brief experience with the rabbit pregnancy test. Accurate results were obtained in all instances.

Contraception : Its Justification and Practice

By DR. ELSA P. WOODROW

(Abstracted from the *South African Medical Journal*, October 22nd, 1932, Vol. VI, p. 653)

CONTRACEPTION, more popularly referred to as birth control, may be defined as the regulation of the birth rate by conscious control of human conception.

From earliest history the various countries of the world have been alive to the dangers of over-population. It was realized that, in a limited area, if the rate of increase was too rapid, the population would sooner or later outgrow the means of subsistence, and the growing pressure had to be relieved from time to time by the voluntary means of 'exposing' children, infanticide, abortion, and occasionally emigration. There were, in addition, frequent wars, epidemics and famines to act as involuntary checks on the increase.

On the other hand, certain conditions, such as improved cultivation, irrigation, and the growth of industry in towns, increased the material resources of the country and made a gradual increase of the population possible.

In the course of the nineteenth century, in countries such as Britain, a colossal change was brought about by the industrial revolution, whereby the enormous increase of material supplies resulting from the export of manufactured goods enabled a huge population to grow up. From 1800 to 1900 the population of England was more than trebled, and in Europe it increased from 187 millions to 400 millions. In the middle Victorian period the birth rate reached its highest peak of 36.3 per thousand.

A hundred years ago Malthus began to study and write upon the subject of population growth, and, in his 'Essay on Population', he advised his generation to avoid the terrible positive checks of famine, disease, infanticide and war by practising the prudential checks of postponing marriage and disciplining themselves in moral restraint after marriage—advice which has not found support from biologists, who for the most part, while acknowledging that some conscious control of conception is highly desirable and necessary, nevertheless consider these two methods as racially and individually bad.

Birth control has always met with considerable opposition from certain sections of the community. 'Race suicide' is a favourite catch-phrase on their lips, and 'Look at France' they usually add, and when we do look at France, as such opponents incidentally very seldom trouble to do, we find that in 1920, France, alarmed at the decrease of her population, accentuated by the ravages of war, passed an Act making the practice of contraception a criminal offence. The objects of this Act were not achieved, in that the number of live births did not increase, but the abortion rate

became appallingly high. Dr. Lacassagne, of Lyons, an eminent sociologist, estimated that the number of abortions in France rose to not fewer than 500,000 in a year, an appalling figure in comparison with the average annual total of 750,000 actual births!

Marcus Rubin, in 1900, in his work 'Population and Birth-rate, illustrated from Historical Statistics', shows that where the birth rate is very high, early mortality is also generally high, and therefore the survival rate is low. It is the survival rate which is the nationally important figure.

The mortality at all ages in Africa and Eastern Asia is far higher than among the less prolific races of Western Europe. It would seem, therefore, that birth control, as the most important alternative to a high death-rate, is an essential factor in human progress, and a necessary condition for the improvement of the racial type. The higher type will always be able to take care of itself against the lower types produced by unlimited procreation.

Birth control has, further, the national advantage of preventing the waste of maternal vitality and the financial outlay incidental to the production of weakly, diseased infants, which only too frequently become a burden to the State in later years, if indeed they survive at all.

Dr. Weinberg, of Munich, has shown by an analysis of 1,045 cases of very poor parents of the same class in Germany the value of spacing births. He found that where less than two years intervened between successive births from the same mother, the chances of life of the infant were almost halved, in comparison with those spaced at intervals of two years or more.

Margaret Sanger, the great pioneer of the birth control movement in the United States of America, shows clearly the difference obtaining in two countries which she visited. In one of these, Holland, birth control had been very generally practised for many years, and in the other, China, it had as yet made little headway.

In Holland the Neo-Malthusian League had, since 1881, established consultation centres all over the country. They were run by nurses and midwives specially trained for the work by Dr. Rutgers and Dr. Aleta Jacobs.

In 1915, when Mrs. Sanger visited the country, she found from the vital statistics that the tables of maternal mortality gave Holland the lowest figure, whereas the United States of America stood at the top of the list; also, the infant mortality rates of the Hague and Amsterdam were the lowest of all the cities of the world. There was no differential birth rate, as advice on contraception was available to all.

To turn now to the other side of the picture—China—I do not think I can do better than quote Mrs. Sanger's own words: 'In China the age-old injunction to increase and multiply had been carried to a literal conclusion. The ancient well-spring of art, philosophy, and the deepest wisdom of the world has been brought down to the lowest conceivable level by the brutal, bestial and squalid breeding of the worst elements of the yellow races. Pestilence, famine and war are the loathsome substitutes for contraception in checking the population growth.'

If the knowledge and practice of birth control could be extended throughout the world, it would not greatly alter the numerical proportion of the nationalities. A decline in the birth rate of each country would strengthen the nation by raising the health rate, substituting quality for quantity.

What we have to contend with chiefly at the present time is the differential birth rate obtaining in the majority of countries populated with Western European stocks. In a recent table of comparative fertility for England, referring only to women of child-bearing age, and taking the general population fertility at the arbitrary figure of 100, we get the following illuminating figures:—

Coal miners head the list with a fertility rate of 126.4. Agricultural labourers come next with 113.4, boiler-

APRIL, 1933]

makers 110.1, farmers 100.5, Church of England clergymen 72, teachers 70.3, and lastly doctors 64.7.

There is only one remedy for this, and that is for the knowledge of birth control, and the facilities for its practice, to be available to all classes and sections of the community in equal measure.

It is a social issue of tremendous importance, and would prove one of the corner-stones in any scheme for the reduction of crime, pauperism, drunkenness and overcrowding. It would release vast amounts of time and money now spent in alleviating distress, ill-health and unemployment.

The movement for birth control has always had the opposition of the Churches to contend with, though their attitude has shown a somewhat less rigid disapproval in recent times.

It is a curious fact that their condemnation of effective methods of contraception is based on a biblical tale, 5,000 years old—the story of Onan, who was told to go and procreate children with his brother's widow, and who because he didn't wish to, had intercourse with her using the method of coitus interruptus to prevent the woman becoming pregnant. And this, we are told, 'was evil in the sight of the Lord, and he was slain'. The Churches have chosen to consider that the evil was the fact that he used a method of birth control, and not the fact that he was averse to following the tribal custom of marrying his deceased brother's widow.

In 1916, before the Birth Rate Commission in England, the Christian Churches, including that of Rome, made the statement that 'where all other deterrents fail, married couples may be allowed to limit intercourse to the intermenstrual period, sometimes called the *tempus agenosos*', or safe period. This, they declared, was 'natural', thus showing their profound ignorance of physiological laws, in that they allowed intercourse to occur when the woman was least inclined for it.

This method they also considered legitimate, because its success was uncertain. The line of reasoning is curious and somewhat obscure. They apparently consider that no sin is committed by using a method of birth control—a bad method too—so long as a loophole is left for the will of God to operate! This is birth control without its courage or science.

However, we have but to look back into history to encounter other similar theological opposition to the advances of science. An eminent divine, preaching against vaccination, declared: 'The law of God prohibits the practice, the law of man and the law of nature loudly exclaim against it'.

When Sir James Simpson fought for the use of chloroform in labour, the clergy were loud in denunciation of this 'unmitigated piece of iniquity'. However, it is good to realize that the Anglican Bishops at the Lambeth Conference of 1930 at last began to accept the modern trend of thought, which maintains that the birth of a child should be a rational process which has been planned and desired, and not merely the haphazard and unwanted result of sexual passion.

In their encyclical letter they declare that though 'there is a very strong tradition that the use of preventive methods is in all cases unlawful for a Christian, it must be admitted that it is not founded on any directions given in the New Testament'. Later on they say, 'We cannot condemn the use of scientific methods to prevent conception which are thoughtfully and conscientiously adopted.'

With regard to the Church's opposition to birth control, it is rather interesting to note that the clergy of the Church of England rival the doctors in their low birth rate, and the clergy of the Church of Rome are celibate.

Lastly, we come to the personal justification of birth control. No member of the medical profession can possibly be in ignorance of the results of unlimited procreation. We have all seen the poor wrecks of humanity that crawl up to the gynaecological departments

of our big hospitals, their lives one long agony of child-bearing, and each month a nightmare lest their periods should not appear. Ill and broken in spirit they come, these drudges of the world, ignored by governments and religions, reduced to a hopeless despair by the much-vaunted glories of motherhood.

It is no wonder that the women of the world have revolted against such abject slavery, that they are demanding to be something more than child-bearing machines, that they are demanding as their right a fuller and healthier life with opportunities for self-development and independence.

The appalling results of unrestricted procreation from the maternal point of view is not the only evil we have to contend with; it is not merely a question of birth control *versus* unlimited procreation, but birth control *versus* abortion.

The tale of self-induced abortions, with its trail of misery and ill-health, and its probable effect on maternal mortality and morbidity in later pregnancies, is a horrible reality.

In the *American Journal of Obstetrics and Gynecology* in the year 1922 it was stated that 'it has been estimated that in New York City alone there are 80,000 criminal abortions annually'.

Margaret Sanger, in the course of her nursing career, which took her into the poorest parts of New York, states she has seen on Saturday nights groups of anything from 50 to 100 women going into questionable offices well known to the community for cheap abortion.

But the world is awakening to the need for the dissemination of information on birth control. In England for ten years there have been clinics established on a voluntary basis in all the large towns, and in 1930 the Ministry of Health published its permissive memorandum allowing married women to be given information on birth control at the clinics, in cases where further pregnancy would be detrimental to health.

Municipal clinics are being established in certain towns for this work, and, in others, a grant is given to the existing voluntary clinics for the treatment of cases referred to them from the health departments.

Clinics are established in the United States, Germany, Holland and Russia.

In Japan, the health department of the city of Tokyo has decided to set up clinics in the municipal health advice stations. Japan is fortunate in that she has no religious conflict on the subject to contend with.

In Shanghai, two leading hospitals have volunteered quarters, staff, and equipment to educate physicians and nurses in contraceptive technique and in the direction of clinics.

In India, a Government birth control clinic has been established at Mysore, and the National Congress of Indian women, who are aiming towards the abolition of the traditional slavery of their sex, have realized that the knowledge of birth control is one of the most powerful weapons in their fight for freedom.

In South Africa, three clinics have been established in the current year. Early in February a clinic was opened in Johannesburg under the auspices of the Race Welfare Society, the mothers' clinic at Observatory was opened on February 15th, and in July a birth control clinic was opened in Pretoria.

Reviews

TREATMENT OF FRACTURES IN GENERAL PRACTICE.—By W. H. Ogilvie, M.D., M.Ch., F.R.C.S. In two volumes. The Pocket Monographs on Practical Medicine. London: John Bale, Sons and Danielsson, Ltd., 1932. Pp. 108 in volume I and from 109 to 180 in volume II. Price, 2s. 6d. each volume.

THESE little books attempt to give a practical outline of fracture treatment in the compass of 180 pages.

They are addressed to those in practice, and therefore the sections on anatomy, pathology and symptomatology have been curtailed to the minimum, in order to leave more space for those on treatment. Readers of 'Recent Advances in Surgery' will expect much from Mr. Ogilvie and they will not be disappointed. In the small space at his disposal he has managed to give an accurate summary of the most modern methods of fracture treatment, which puts to shame all the textbooks in general use. This branch of surgery has made great advances in recent years, owing to the more general adoption of methods of skeletal traction, made possible by the introduction of the Kirschner wire and the Steinmann pin. The teaching of Böhler has been adopted to a considerable extent, but the splints advocated are those familiar to British surgeons and the author is cautious in his recommendations for the use of unpadded plaster casts, though he advocates them for fractures of the leg and ankle he is not prepared to follow Böhler in other cases. For instance in difficult fractures of the radius and ulna he recommends operation in preference to traction combined with unpadded plaster casts, as safer, more scientific and allowing more perfect anatomical restoration. The teaching in this book is thoroughly sound and the amount of information compressed into such a small space is marvellous. The illustrations are rather rough drawings, but are very clear, it is a pity that figure 28 in volume II should be given as the treatment of fracture of the femur, whereas the treatment described in the text is correctly represented by figure 13, volume I; the former figure depicts a method now regarded as inferior. The book is one which may be strongly recommended to all practitioners.

W. L. H.

SURGERY.—By S. K. Sen, L.R.C.S., L.R.C.P. (Edn.), L.R.F.P.S. (Glas.). Vol. III. First Edition. Published by the Surgical Education Society, Ltd., Calcutta, 1931. Pp. iii plus 348. Illustrated. Price, Rs. 7-8 (per single volume).

THIS volume deals with surgery and pathology of growths. It consists of about 400 pages and is divided into six chapters. The description of the different varieties of tumour is very lucid and interesting. The subject-matter has been dealt with in a novel way, quite different from what we see in ordinary textbooks. The author's classification of growths into blastomatoids and blastoma is new, but it is for the pathologists to say whether this classification is sound or not. The summary at the end of each chapter and the marginal notes will help the readers to revise the subject. It is well illustrated and the author is congratulated on having a beautiful collection of photographs of his own cases. We miss very much the microscopical sections which should have been incorporated.

The get up of the book is nice, the type is good, but there are some spelling mistakes and repetitions of the same subject. We hope these will be rectified in the next edition.

The last chapter dealing with 'Diagnosis of Swellings' is really instructive.

S. N. M.

THE RATIONAL TREATMENT OF VARICOSE VEINS AND VARICOCELE.—By W. Turner Warwick, M.A., M.B. (Cantab.), F.R.C.S. (Eng.). Published by Messrs. Faber and Faber Ltd., London, 1931. Pp. 188. Illustrated. Price, 5s.

THIS is an excellent handbook consisting of 179 pages and divided into two parts each part having four chapters. The first part deals with the aetiology of varicose veins and the various theories in relation to this subject have been described briefly. The normal venous return, the connection between the superficial, perforating and the deep veins have been satisfactorily explained.

The second part deals with the different methods of treatment at present in use, both by operation and by injection. The author has fully described the actual procedure of the injection treatment, the various sclerosing solutions which are being used, their advantages and disadvantages, the emergencies that may occur and how to meet them. The appearance of this handbook in addition to similar handbooks on this subject shows the popularity of the injection treatment of varicose veins. The subject-matter is very thoughtfully conceived and the bibliographical references at the end of the book are very exhaustive and will be of great help to those who want to make a special study of the subject.

S. N. M.

ACUTE OTITIS MEDIA.—By W. M. Mollison, C.B.E., M.A., M.Ch., F.R.C.S. London: John Bale, Sons and Danielsson, Ltd., 1932. Pp. 71. Illustrated. Price, 2s. 6d.

THIS pocket monograph on acute otitis media and its complications, designed as a handy aid to the general practitioner, is sure to fill a want. Its seven chapters clearly written give not only an account of the anatomy of the middle ear, but also deal with the pathology of and types of acute middle ear disease with their treatment.

The last two chapters are useful ones in so far as the one places before the mind of the general practitioner in a concise way the complications that might arise in the course of an acute otitis media, and the other deals with acute mastoiditis and its complications.

The author is to be congratulated upon the complete way in which he has dealt with the subject in so short a space.

N. J. J.

THE DISCHARGING EAR.—By A. G. Wells, B.S., M.B., D.P.H., J.P., Barrister-at-Law. London: John Bale, Sons and Danielsson, Ltd., 1932. Pp. x plus 92. Price, 2s. 6d.

THE pocket monograph, *The Discharging Ear*, sets out very clearly the common causes of aural discharges and should be a great help to the general practitioner in the diagnosis of the various conditions which might lead to an aural discharge. The chapters are well written and an excellent account is given of the diseases of the external auditory meatus, the tympanic membrane, the middle ear and the mastoid process.

The paragraphs on treatment are particularly good and tell the general practitioner definitely what in the author's experience are the things to do.

The little book, I have no doubt, will be an acceptable addition to the literature already existing on the subject.

N. J. J.

ON THE CONSERVATION OF THE LYMPHOID TISSUE OF THE UPPER RESPIRATORY TRACT.—By T. B. Layton, D.S., M.S. (Lond.), F.R.C.S. (Eng.). Published by Ash and Co., Ltd., London, 1931. Pp. 46. Price, 1s.

MR. T. B. LAYTON in this monograph admirably argues the points in favour of conservative treatment. It must be admitted that operations for the removal of tonsils and adenoids are often hastily advised and alas more frequently done than is necessary. The author is to be congratulated upon the way in which he has proved the importance of the lymphoid tissue of the upper respiratory tract and the respect we should pay it. This little pamphlet should go far to lessen the wholesale practice of removing tonsils and adenoids which unfortunately exists to-day.

N. J. J.

LIPPINCOTT'S QUICK REFERENCE BOOK FOR MEDICINE AND SURGERY.—By G. E. Rehberger, A.B., M.D. Eighth Edition. Rev. ed. Philadelphia and London: J. B. Lippincott Company, 1932. Illustrated. Price, 65s. (Obtainable from Butterworth and Co. (India), Ltd., Calcutta.) Price, Rs. 48-12.

It is only a little less than two years ago since the seventh edition of this book was reviewed in these columns (vol. lxvi, p. 406). On this occasion we described it as the ideal book for the one-book medical practitioner. Very little change has been noted in the present edition. Additions and changes have been made in a few sections, including the sections on Addison's disease, angina pectoris, ascariis infection, brain abscess and injury, nervous dyspepsia, chronic colitis, vitamins, snake bite, syphilis, varicose veins, the diagnosis of pregnancy, erysipelas, oriental sore (but regrettably not kala-azar, though we drew attention to the defect in this section in our last review), radiography of the urinary tract, and rabies.

One cannot fail to be impressed by the general usefulness of the book. The very effective coloured illustrations of skin diseases and rashes, which the printed word is so powerless to describe, is perhaps the most outstanding feature of the book.

In recommending this book to the mofussil practitioner in India it is a pity that we are compelled to qualify our recommendation by saying that he will find it advisable to have another book on tropical diseases; with this qualification we recommend it whole-heartedly.

AN ATLAS OF SKIN DISEASES IN THE TROPICS.—By E. C. Smith, B.A., M.D. (Dublin), D.P.H., D.T.M. & H. (Eng.). London: John Bale, Sons and Danielsson, Ltd., 1932. Pp. 60, with 253 figures in the text and 2 coloured plates. Price, 21s.

This atlas is composed of photographs and microphotographs of skin diseases that have been seen by the author in Nigeria. They have been well selected and considering the limited area from which they have been collected they represent a great variety.

All of the photographs are not of tropical diseases, such diseases as syphilis and tuberculosis being depicted; perhaps the best collection of photographs of a single type of disease are those devoted to ringworm. The author states in his preface that dark skins lend themselves well to photography for the purpose of displaying skin lesions and this is amply borne out by his results.

The letterpress is very brief, but with the accompanying photographs a good idea of most of the conditions is given. The book would have been easier to use if the numbers of the figures dealing with a particular disease had been placed at the beginning of the written description instead of in a list at the beginning of the book. Treatment is in many instances not mentioned at all and where it is included it is much too brief to be of use to any but the expert dermatologist.

Although the atlas is to a certain extent limited in its appeal to tropical practitioners in general, by the omission of diseases not seen in Nigeria, most of the diseases illustrated in the book are so widespread in the tropics that it will be a useful book to have at hand for ready reference wherever one may be practising.

In a book professing to describe the skin diseases of West Africa, it is surprising to find that there is no mention of crav crawl, not even as a synonym of scabies.

P. A. M.

SURGICAL PATHOLOGY OF THE FEMALE GENERATIVE ORGANS.—By A. E. Hertzler, M.D. Philadelphia and London: J. B. Lippincott Company, 1932. Pp. xxi plus 346, with 285 illustrations. Price, 21s. (Obtainable from Butterworth and Company (India), Ltd., Calcutta.) Price, Rs. 15-12.

This is the fourth of this series of monographs, which when completed will make a very fine and complete

encyclopædia of surgical pathology. The author claims that he has confined himself to his own experience; this has been a remarkably wide one. The book amounts to a very elaborate notebook of the life's experience of a surgeon, as far as this experience applies to the female generative organs. Every pathological condition is illustrated by a photograph or drawing of the part prior to operation, of the organ or tumour after removal, and usually of the histological section of the diseased area. A nice proportion has been maintained and the rarer conditions are dismissed with a few brief notes on the incidence, the symptomatology, the gross pathology, and the prognosis, whereas in the commoner conditions these matters are dealt with at greater length and other aspects, such as ætiology and histology, are included in the discussion.

The book is written by a surgeon, very definitely for surgeons. It is perhaps unnecessary in these days to impress upon the would-be surgeon the importance of a thorough knowledge of pathology. If any doubt remains on this point, one illustration in this book should serve to convince the doubter; this is an illustration of a carcinoma of the body of the cervical canal. Six months before removal, the cervix was found to be smooth and curettings from the body of the uterus showed no carcinoma; from the illustration it is easy to see why. By the time the uterus was removed it was too late to stop recurrences; an earlier removal would probably have effected this.

The book will form a valuable addition to the library of the general surgeon or the gynaecologist.

DIAGNOSIS AND TREATMENT OF DISEASES OF THE THYROID GLAND.—By George Crile and Associates. Edited by A. T. Rowland. Philadelphia and London: W. B. Saunders Company, 1932. Pp. 508, with 164 illustrations. Price, 32s. 6d.

THE compilers of this new book on the thyroid gland do not claim that it is a formal treatise on the subject, but an account of the experience of the Cleveland Clinic with the diseases of this gland. Nevertheless, as the members of this clinic are open-minded workers who have not hesitated to use the experience of their confrères in other parts of the world to add to their own, and as every aspect of the subject is dealt with by one or other of the contributors, the book does in fact amount to a treatise on the subject.

The chapter on iodine and the thyroid gland forms a very satisfactory introduction. The figures that appear in this chapter give one a clear idea of the histology of the various forms of thyroid disease, and there is an excellent summary of our present knowledge on the association between iodine and goitre.

There are 39 chapters, so that it is quite out of the question even to give the chapter headings here. The chapters on operative technique are very well illustrated and each step in the operative procedure is given in detail. American workers have a way of ignoring work done in India; it is, therefore, gratifying to see that McCarrison's work has been referred to freely. The authors have produced a valuable reference book on thyroid disease.

THE BIOCHEMISTRY OF MEDICINE.—By A. T. Cameron, M.A., D.Sc., F.I.C., F.R.C.S.E., and C. R. Gilmour, M.D., C.M., F.R.C.P. (C.). London: J. & A. Churchill, 1933. Pp. x plus 506, with 31 illustrations. Price, 21s.

THIS book is the result of a happy co-operation between two authors, one a professor of biochemistry and the other a professor of medicine and clinical medicine. It is designed both for the student of medicine receiving clinical instruction in the later years of his course, and for the physician who received no special instruction in the medical applications of biochemistry. The modern system of specialisation divides the different branches of study into water-tight compartments and it is often difficult for the student to receive sufficient direction to enable him to co-ordinate pure biochemistry with its different applications to medicine.

A book of this kind is designed to help such a co-ordination. Again, modern medical literature contains a large volume of papers dealing with the biochemical studies of diseased conditions and it is becoming increasingly difficult for one to be abreast of the advances of medical science. This book is, therefore, the more welcome to one who desires to keep himself informed about the outstanding biochemical work which has contributed definite facts of value to medicine. The authors have introduced a small amount of biochemistry of the normal man in order to make the biochemistry of the pathological states more intelligible to the reader. After introducing the normal carbohydrate metabolism, the normal metabolism of fats and other lipoids, the different types of non-diabetic glycosurias, the sugar-tolerance curves and their significance have been discussed. The subject of diabetes mellitus has been treated in fair detail. The abnormal metabolism of fat (other than in diabetes), the normal and abnormal metabolism of water (including a discussion on oedema, albuminuria, nephritis, uræmia, etc.), the metabolism of inorganic compounds and ions, respiration and respiratory disorders, the functions of the organic compounds of blood and diseases associated with them (like anaemia, jaundice, etc.), the endocrine secretions and their functions, the vitamins and vitamin-deficiency diseases, and finally the gastric functional tests and liver functional tests form very interesting reading. A short summary at the end of each chapter helps the reader to recapitulate the important facts discussed in each and there is a short bibliography at the end of each chapter dealing with the recent literature on the subject. Rather more space than necessary has been devoted to the rarer anomalies of disease at the expense of the commoner ones, but the authors point out that many of these rarer conditions and diseases are found to be less rare now that adequate biochemical tests for their detection are being employed, and further, little or nothing of value can be said, biochemically, concerning many of the commoner diseases, like tuberculosis, cold and cancer. Although there are some good books on allied lines the present volume is a welcome addition to medical literature. It will not only help a more intelligent study of medicine in the light of the most recent advances of biochemistry, but will stimulate newer ideas of research.

S. G.

PREVENTIVE MEDICINE.—By M. F. Boyd, M.D., M.S., C.P.H. Fourth Edition. Philadelphia and London: W. B. Saunders Company, 1932. Pp. 532, with 149 illustrations. Price, 22s.

THIS is a book intended primarily for medical practitioners in the United States of America. It will be remembered that the General Medical Council of Great Britain in their review of the medical curriculum in 1920 stated in regard to the teaching of hygiene and preventive medicine, that these were principles and concepts and not merely 'subjects', and that the teaching of preventive medicine should permeate the whole of medical education. The general practitioner must develop the preventive outlook, and preach and practise it in his profession. In the United Kingdom, the practitioner has already been brought into the scope of preventive medicine by his obligatory participation in much of the legislation of state medicine. In this connection one can instance the National Insurance Act, the Notification of Births Act, the Tuberculosis Regulations, the Factories' Acts, the Venereal Diseases Act and Regulations and many others. In the United States of America, legislation in state medicine has not yet included the general medical profession so comprehensively. The application of preventive medicine in every-day life has rather come from the large insurance agencies like the Metropolitan Insurance Company, which now has a large number of medical practitioners on its staff carrying out preventive medical examinations and inculcating principles of health and preventive medicine amongst their clients. This is all

to the good, and one frequently sees the opinion expressed in the United States, that the physicians there are neglecting their opportunities in preventive medicine, and that if this neglect continues the opportunities will lessen, and the field will be taken away altogether from physicians by a changing public sentiment.

The book under review is intended to supply the student of medicine and the general practitioner of medicine with the minimum knowledge of the subject which they should be expected to possess. In this Dr. Boyd has we think succeeded admirably. The salient and important facts of personal and communal hygiene are presented interestingly and shortly, and the book is saved from being a mere summary by the excellent style of the author, and by the authoritative view he is entitled to express not only as a malarialogist, but as a member of the Public States Board of Health. Students of public health in any country will find the book very useful as an up-to-date record of essentials. There are many excellent illustrations which enhance its value. The printing, paper and binding are excellent.

A. D. S.

MICROSCOPIC SLIDE PRECIPITATION TESTS FOR THE DIAGNOSIS AND EXCLUSION OF SYPHILIS.

—By B. S. Kline, A.B., M.D. London: Baillière, Tindall and Cox, 1932. Pp. 99 plus xviii, with 28 figures in the text. Price, 13s. 6d.

IN this small work the author describes his precipitation test for syphilis, the first paper on which was published in 1926. His test is a modification of Kahn's test, though the antigen is somewhat differently prepared. The Kline test is performed microscopically. A critical discussion of the contents of this work would raise the large question of the relative advantages of the Wassermann and flocculation tests for syphilis, which would be out of place in a brief review. The main question in the diagnostic use of the flocculation tests is what clinical value to attach to comparatively small differences in the degree of flocculation. In this, experienced interpretation no doubt plays a great part. Some of the author's technique is decidedly ingenious and he has carried out a useful piece of research in investigating the optimal conditions for flocculation tests. We are not convinced that there is any great advantage in performing flocculation tests for syphilis microscopically, except possibly in infants where there is difficulty in obtaining sufficient serum for tube tests by drawing blood from a vein. Nor do we see much advantage in a very rapid test. 'Immediate' diagnosis of syphilis is only exceptionally of value, e.g., in the testing of a blood donor or in the examination of urgent conditions such as cerebral thrombosis. Apparently the Kline test is as good as any other flocculation test. The value of the tables on pp. 70 and 71 showing comparative results with the Wassermann and Kahn tests is greatly reduced by the fact that more than seventy-five per cent. of the sera examined were from non-syphilitic conditions. It is evident that the larger the proportion of non-syphilitic sera in any series, the greater the percentage of concordance between the results of the tests examined is likely to be. The illustrations are good, but we frankly do not care for the type of diagram favoured by the author. Some of the diagrams, e.g., that on p. 2, seem more suitable for elementary lectures than for inclusion in a work which is intended for specialists. The book is well written, the practical directions are clear and there is much which will repay careful study. A word of praise is due to the publishers for the convenient format and good appearance of the work.

R. B. L.

CLASSIC DESCRIPTIONS OF DISEASE.—By R. H. Major, M.D. London: Baillière, Tindall and Cox, 1932. Pp. xxvii plus 630, with 127 illustrations. Price, 30s.

THE author claims that he was stimulated to write this book by reading *Selected Readings in Pathology*

and *Selected Readings in the History of Physiology*. It was certainly his experience with these two books which led the reviewer to undertake his present task.

This book is larger and its scope is wider than that of the other two books mentioned above. The readings are not arranged historically, but in sections each dealing with a different group of diseases, e.g., Infectious Diseases, Diseases of Metabolism, etc. Needless to say the grouping is done according to our present-day knowledge not according to the state of knowledge at the time many of the writings were dated, in most instances, but there are exceptions; for instance under the heading 'Respiratory Diseases' is a description of Cheyne-Stokes breathing, by Hippocrates, in what appears to be a case of blackwater fever. Except for a few facsimile reproductions the descriptions which were not originally in English are translated.

For no very obvious reason Paracelsus has always made a particular appeal to the imagination of the reviewer; he has always felt that a man who was born with the names Theophrastus Bombast von Hohenheim, who added the names Philippus Aureolus, and who then adopted the pseudonym Paracelsus was no ordinary individual. This sixteenth century physician has received a considerable amount of attention in this book and his writings on cretinism and endemic goitre have been reproduced extensively, to the great satisfaction of the reviewer.

There are a few criticisms to be made. The author has not adhered to the scope defined in the title. There seems to be very little justification for bringing Banting into a book entitled 'Classical Descriptions of Disease'; however epoch-making was Banting's work, none of it could be classified under this heading. Still, the fault, if it exists, lies in the title and not in the book. This constitutes a very important contribution to the history of medicine, and we must congratulate the publishers on adding this to their already imposing list of books chronically the milestones in the advance of medical science. The format of the book is particularly pleasing; the sombreness of the ordinary medical book has been avoided without an undue lapse into frivolity.

L. E. N.

A SHORTER HISTORY OF SURGERY.—By Sir D'Arcy Power, K.B.E., F.R.C.S. (Eng.). London: John Bale, Sons and Danielsson, Ltd., 1933. Pp. 91. Price, 3s. 6d.

THIS is a very small book—of about 25,000 words. It amounts to little more than an essay on the subject. It is however a very well-balanced essay and it should certainly achieve the object for which it was written, namely, to give the reader a taste for more—it is in fact a sort of *hors d'œuvre*.

The history of surgery is essentially the history of medicine, up to the beginning of the 19th century; from that date onwards specialization began to creep in. There are some very unpleasant patches in this history up to the time of Lister. His introduction of antiseptic methods coincided more or less with the introduction of anaesthesia, and from this time onwards the march of surgery has been triumphal.

The book contains little new matter, but the old matter it presents in a concise and pleasant manner. We can strongly recommend it to our readers.

L. E. N.

1. MODERN BIRTH CONTROL METHODS OR HOW TO AVOID PREGNANCY.—By G. R. Scott, F.P.H.S. (Eng.), F.Z.S. London: John Bale, Sons and Danielsson, Ltd., 1933. Pp. x plus 209. Price, 7s. 6d.

2. EUGENICS AND BIRTH CONTROL.—By Mercia Heynes-Wood (Mrs. Cedric Dover). Second Edition. Lahore: The Times Publishing Co., 1932. Pp. 119. Price, Rs. 3.

THE literature on birth control is enormous and is added to almost daily. The sale for books on this

subject must be equally large or the law of supply and demand would operate and stop the flow.

Mr. Scott's book is like many others, but on the whole it is a very satisfactory book. It lives up to its title, and its sub-title, 'How to avoid pregnancy'. Little time is spent in discussing the ethics of birth control; the author goes straight to the point and describes various methods, giving their *pros* and *cons*. He ends with a table covering some 12 pages, in which the indications, the contra-indications, the reliability, etc., of the different methods are given. One interesting feature is that the writer does not condemn, except on the grounds of unreliability, *coitus interruptus*, as most writers do; his reasons seem sound enough.

The fact that there was a foreword by Sir W. Arbuthnot Lane did not increase the reviewer's confidence when he undertook his present task, nor in his opinion has the foreword added to the value of the book; many people will disagree with this prolific contributor to the lay press when he states that a man's or a woman's general usefulness in the world is in proportion to his or her sexual development. Otherwise, the book is a practical one and can be recommended.

Mrs. Dover's book is written for the Indian public, both domiciled and indigenous. The subject is discussed mainly from the point of view of India, and the wider aspects of the problem of population control are dealt with. A number of pages are devoted to the technique of birth control, but there do not seem to be any methods particularly suitable for the Indian ryot, who, if it is population control rather than birth control that is the desired goal, is the person to whom the methods must be applicable. The author has taken a sane view of the subject and the book should prove useful.

SIMPLIFIED DIABETIC MANAGEMENT.—By J. T. Beardwood Jr., A.B., M.D., F.A.C.P., and Herbert T. Kelly, M.D., A.A.C.P. Philadelphia and London: J. B. Lippincott Company, 1932. Pp. 191. Illustrated. (Obtainable from Butterworth and Co. (India), Ltd., Calcutta.) Price, Rs. 4-8.

SIR Dr. Lawrence described his 'line ration' scheme in the dietetic treatment of diabetes, several other simplified processes for the calculation of diabetic diets by the rule-of-thumb method have been advocated.

The special feature of this little book lies in what the authors describe as the 'unit method' of measurement of diabetic diet. According to the authors, this system of measurement, when used in conjunction with the diet-prescription charts given in the book simplifies calculation of the diet from the doctor's point-of-view and makes the actual measurement of the diet easier for the patient.

The method is spread over three groups which are called A, B, and C. In group A, each unit consists of 5 grammes of carbohydrate and 1 of protein, having a caloric value of 24. In group B, each unit consists of 5 grammes of protein and 10 of fat, having a caloric value of 110. In group C, a unit consists of one unit of group A and one of group B, or 5 grammes of carbohydrate, 6 of protein and 10 of fat, with a caloric value of 134.

The book is divided into three chapters. In the first chapter the author has dealt with general considerations, so as to enable the patient to co-operate intelligently with his doctor. Chapter II deals with the symptoms, the diagnosis and the treatment of diabetes including complications that arise. In the last chapter, the author has mainly dealt with the 'unit' method of calculating diabetic diet and has given illustrated charts together with specimen diet charts and diabetic recipes.

The book should prove to be of interest to both diabetic patients and doctors.

J. P. B.

MATERIA MEDICA FOR NURSES.—By A. Muir Crawford, M.D., F.R.F.P.S.G. Second Edition. London: H. K. Lewis and Co., Ltd., 1933. Pp. viii plus 89. Price, 3s. 6d.

THE second edition of this book will be welcome to members of the nursing profession. It is a small book covering about 100 pages, written in an easy and readable style. The author has used considerable judgement in selecting only drugs in common daily use with their important preparations, doses, actions, and therapeutic uses. *Materia medica* is a vast subject, growing every day in volume, and it is no easy matter to pick out only the essential requirements for the nurses without going too far into the unnecessary details. The chapter on classification of drugs according to the part of the body upon which they act is worth special mention. The table of important doses at the end will be useful for ready reference. Several drugs included in the new edition of the British Pharmacopœia have found a place in the book. It can be recommended as a good textbook for nurses.

R. N. C.

THE BREAST-FED BABY IN GENERAL PRACTICE.—By L. G. Housden, M.B., B.S. (Lond.). London: H. K. Lewis and Co., Ltd., 1932. Pp. viii plus 118. Price, 4s. 6d.

STATISTICS of the admission of infants to the medical wards of the Great Ormond St. Children's Hospital are convincing evidence of the value of breast feeding. Of the babies admitted 88.5 per cent. were bottle fed and only 11.43 per cent. breast fed. Figures indicating such a high degree of morbidity amongst artificially-fed babies should cause the family doctor to pause and consider before countenancing or actually encouraging the mother to wean her baby. The immediate results of artificial feeding are, perhaps unfortunately, often

good, and it is certainly easiest and most time-saving for the busy practitioner to recommend a bottle, but there are many cogent reasons against it and Dr. Housden should have little difficulty in accomplishing the object of his book, namely, to pass on his conviction alike of the necessity and the possibility of promoting breast feeding even in a busy practice.

He deals practically with the causes of failure, the difficulties encountered in general practice, the management and technique of successful feeding, and the anxieties aroused by breast-fed babies. He has some interesting observations to make on the best time for the first feed, and advocates as a result of experiment that it should not be given earlier than 24 hours after birth. The chapter on methods of increasing the quantity of milk secreted contains a fairly complete account of a new method—the hypodermic injection of 1 cubic centimetre of human milk—which Dr. Housden has found to be of definite value in selected cases.

Vitamine A is said to be found in oils without any qualifying adjective, and cows' milk is said to be four times as rich in iron as human milk, whereas it contains half to one-third as much.

The essay, 'Studies in breast feeding', incorporated in *The Breast-fed Baby in General Practice*, was awarded the Sir Charles Hastings' clinical prize by the British Medical Association in 1932. That is sufficient evidence of its value and usefulness, and the book needs no other recommendation.

J. M. O.

PATHY BIDHI, OR DIET. (Written in Bengali).—By B. B. Pal, L.M.S. Published by Dr. B. B. Pal, L.M.S., Armanitola, Dacca, 1932. Price, Re. 1-8.

THIS little volume sets forth clearly and concisely useful hints regarding the diet in relation to different common ailments of the body in Bengal.

S. P. B.

Annual Reports

THE ROCKEFELLER FOUNDATION: ANNUAL REPORT FOR THE YEAR 1931. NEW YORK.

FOLLOWING its extensive early hookworm programme and its emergency tuberculosis work in France, the Foundation in 1920, or a little over ten years ago, began to participate in the public health work that was being re-established on a peace-time basis in many parts of the world. Two general purposes have underlain the many forms of public health work in which it has participated: the first of these is the acquirement of new knowledge in hygiene and public health by field and laboratory research; the second, extension of such knowledge through application of what is already known. In a number of countries there has been brought about, partly through the Foundation efforts, a considerable investment in men, ideas, buildings, and equipment, now representing a constructive force in the public health work of the world.

During 1931 the Foundation assisted the governments of forty-seven countries throughout the world and the health administrations of thirty-seven states in the United States in carrying on public health work. Aid was given to local as well as central health services. Contributions were continued to the Health Organization of the League of Nations, which is active in the international interchange of public health personnel and in maintaining a world-wide system of public health statistics and an equally wide service of epidemiological intelligence. In addition, the Foundation engaged in certain activities in connection with tuberculosis, respiratory diseases, undulant fever, and anæmia, and in epidemiological studies and studies of sanitation and public health service.

Yellow fever

When for the first time in history a laboratory animal, the rhesus monkey, became available for yellow fever studies, the disease itself began to yield some of its secrets. It was revealed as a virus disease which could henceforth be properly classified with other virus diseases, of which there are a great many in the plant, animal, and human worlds, two of the most common being smallpox and the ordinary cold. An even more important revelation was that of its wide-spread existence in mild form, impossible of detection by ordinary medical methods. It became clear that the conspicuously successful campaigns referred to above had dealt with yellow fever in its virulent form, the form it takes when it leaves its native lair and rages among new, non-immune populations; they had but pushed the disease back into the remoter parts of the world from whence it had come. The insidious nature of yellow fever masquerading as a mild affection among distant native populations stood out as a new factor. With the further aid of the monkey there was made the beginning of an attempt to chart the regions in which this mild form of yellow fever lurks and from which it may at any time break forth to work its well-known havoc among the other populations of the world. There is, moreover, full realization that this danger has been enormously increased by the greater rapidity of land, sea, and air travel and the rising susceptibility of populations in regions which have been freed of yellow fever.

The hazards attending any attempt to beard yellow fever in its own den, both in Africa and in certain regions of South America, have been amply demonstrated

by the numerous deaths occurring among scientists engaged in this task. Some method by which it might be possible to interrupt this series of deaths among laboratory workers has been urgently needed, and there is every indication that a good step forward in this direction has been taken by the development of a new vaccine against yellow fever, based directly on the use of white mice. It is a pleasure to note that this year The Rockefeller Foundation does not have to report any deaths from yellow fever among its personnel. No fatalities from the disease occurred among the staff during 1931.

The first vaccination of a human being against yellow fever by the new method occurred on 13th May, 1931. Thus was brought to swift preliminary fruition the yellow fever laboratory work with the mouse, the second animal to help man in his conquest of yellow fever.

Yellow fever in the mouse bears little resemblance to yellow fever in man. In the mouse it takes the form of an encephalitis. In this animal the virus is neurotropic, instead of viscerotropic as in man.

The next step was to stabilize the virus, so that scientists would have available a substance which was uniform in its reactions and capable of producing the desired effects with certainty. After many passages through mice, the virus becomes highly virulent for these animals, and the incubation period becomes short and constant. At the same time the virus loses its power to kill rhesus monkeys, although it does continue to produce fever in these animals; in other words it assumes the character of what is known as a fixed virus.

With a virus having stable and dependable qualities it was possible to develop further a protective procedure involving inoculation with yellow fever virus and the simultaneous administration of yellow fever immune serum. It was shown that these combined infections developed active immunity in monkeys. Presumably they would do the same to human beings.

This has been verified. Between 13th May and 29th June, 1931, ten persons were vaccinated. Before vaccination the sera of these persons were without protective power, i.e., they did not protect from death animals inoculated with yellow fever virus. After vaccination the sera from these persons, in every case, had protective power against yellow fever virus both in monkeys and in mice. Persons who have been vaccinated are in the same class as persons who have had yellow fever. Since it is well-known that anyone who has survived an attack of yellow fever is immune to the disease for the rest of his life, vaccinated persons are presumably similarly protected, but time will be required to determine with exactness the duration of their immunity.

According to the latest information, sixteen persons have been vaccinated against yellow fever in the Foundation's yellow fever laboratory in New York, and in addition three persons in Nigeria and Brazil have been immunized with material sent from this laboratory. Vaccination has so far been tried only on persons engaged in yellow fever laboratory or field work. The aim has been to give immediate protection to the small group of highly exposed workers. Immunization or protection is produced by a single injection of a dried mixture of yellow fever virus fixed for mice and human immune serum, with separate injections of additional serum to make up the amount required for protection. The immunizing substance can be shipped from the laboratory and used elsewhere, as was actually done in the three cases referred to above. The amount of serum required in vaccination varies as the body weight and seems to be independent of the virulence of the strain used.

The immunizing reaction after vaccination seems to be part of a true infectious process. So far as protective power is concerned, it has an effect similar to that of an attack of yellow fever. What we have now is a reasonably safe method of producing demonstrably active immunity in human beings. It has been shown in tests that the mixture of fixed virus and immune

serum retains its immunizing power for eight months when dried in a frozen state and sealed in glass.

The Rockefeller Foundation's research work on yellow fever is carried on in three laboratories; one of these is located in West Africa, at Lagos, Nigeria, another at Bahia, Brazil, and the third in New York City.

In addition to its laboratory and field research on yellow fever, the Foundation has from year to year been active in control work. During 1931 it assisted the government authorities of Brazil in extensive preventive operations against the disease.

Since most of the work for the control of yellow fever intimately touches the life habits of the mosquito, a considerable amount of effort has been directed toward increasing knowledge of the insect carrier of the disease. As was explained in the report of The Rockefeller Foundation for 1930, a number of mosquitoes other than *Aedes aegypti* have been found capable of transmitting yellow fever and may therefore enter the picture so far as control work is concerned.

During 1931 *Culex (Culex) thalassius* Theobald was definitely added to the incriminated list, and *Mansonia (Mansonioides) uniformis* Theobald was found to produce the disease when emulsified and injected subcutaneously into rhesus monkeys. Investigation of these species of mosquito was deemed important because they are abundant in certain sections of West Africa, because they enter houses, and because they bite man with great frequency.

Culex thalassius proved to be an inefficient vector in comparison with *Aedes aegypti*. However, the density of the species is known to be very great at certain places and this may compensate to some extent for its relative inefficiency, making it of some importance epidemiologically. *Mansonia uniformis* could not be kept alive in captivity long enough to demonstrate conclusively its ability to transmit yellow fever by biting, but compared with *Aedes aegypti* it also is not an efficient vector, although it may play a part in yellow fever epidemiology in places where the species is abundant.

The question of the effect of temperature on mosquito breeding is of importance in explaining the fact that yellow fever does not become endemic in certain parts of the world. At the Bahia laboratory experiments were performed on colonies of *Aedes aegypti* mosquitoes to determine the effect of different temperatures on their vital activities. It was found that at 36°C. the colony was unable to maintain itself in the second generation, the high temperature shortening the life of the adults, diminishing blood-sucking, and destroying fertility. At 19°C. conditions were apparently favourable. At 18°C. the mosquitoes did not feed well, but vital activities were continued at a pace adequate for the maintenance and even increase of the numerical strength of the colony.

In the literature dealing with the effect of cold weather in limiting the propagation and spread of yellow fever through failure of the mosquito host, attention has been directed chiefly to the adult stage of the insect and secondarily to the larval and pupal stages. Experiments to determine the effect of cold and heat upon fresh and matured stegomyia eggs were conducted at the Bahia laboratory. It was demonstrated that actual freezing kills practically all eggs of both types after relatively short exposure and that very high temperatures have an injurious effect, especially upon fresh eggs. Exposure to temperature of 40°C. to 45°C. killed stegomyia eggs rapidly. Matured eggs were slightly most resistant than fresh. In nature, unfortunately, probably the majority of eggs are deposited in-doors or in sheltered places where they are not subjected to extreme temperatures.

Another series of experiments in the laboratory in Bahia was devoted to determining whether modifications in temperature would affect the length of time required for incubation of infective yellow fever virus in *Aedes aegypti*. It appeared that the period was shortened at high temperatures and prolonged at low

temperatures. There was no loss of virulence in the virus even when the mosquitoes had been kept for four weeks at 8°C. and later subjected to 36°C. for six days.

From further experiments with *Aedes aegypti* in West Africa, it appears that the transfer of yellow fever virus from infected females to copulating males occurs in nature so infrequently that the possibility need not be considered as a factor in the perpetuation of the disease. This conclusion supports other evidence that yellow fever virus in infective quantities cannot be maintained indefinitely among mosquitoes without some suitable intermediary host.

The actual nature of yellow fever virus is as yet little known. There is doubt about its chemical composition, its physical structure, and even about whether it is alive or not. In a series of experiments, rabbits were inoculated repeatedly with active yellow fever virus contained in mosquitoes and in monkey serum. It was thought that if the rabbits developed precipitins against the virus, this would indicate that the virus is protein in character. However, the virus of yellow fever in mosquitoes was found to engender in rabbits neither precipitins nor protective bodies against the same virus contained in monkey blood. Large amounts of the virus from the blood of infected monkeys also failed to engender in rabbits demonstrable precipitins against the virus in mosquitoes. There were engendered in relatively small amounts protective bodies against monkey blood virus. It would seem that mosquito virus differs qualitatively from monkey blood virus in its power to engender protective bodies in rabbits. However, it cannot be said that definite conclusions are as yet warranted.

An attempt was made to throw light on the nature of the reaction by which yellow fever immune serum protects animals against infection. Electrophoresis experiments completed during the year indicate that the virus of yellow fever travels toward the negative pole in alkaline fluids and toward the positive pole in acid fluids. Yellow fever virus appears to travel with hæmoglobin regardless of charge and to be inactive in fluids that have more than certain degree of acidity.

The yellow fever virus is extremely labile and is changed or destroyed by the most minute and undetermined changes in the culture medium. But it is possible to grow the virus indefinitely in the laboratory in the presence of living tissues by methods successfully developed for other filtrable viruses.

The possibility of low fatality rates in natives of endemic or previously endemic areas must be taken into consideration in studying the distribution of yellow fever. In other words, the disease may occur quite generally in light form. A large part of the native population seems to be able to develop immunity without having the symptoms of the disease. This phenomenon is not limited to the black race. Some investigators suggest that this may be an hereditary immunity or at least an hereditary resistance. This would mean that the inhabitants of endemic areas are inheriting the protective mechanism.

Malaria

In West Africa an experiment was made to determine whether mass treatment with plasmochin, would be a practical antimalaria measure. Small doses of the drug were administered. Before this was done, in the spring of 1931, 1,350 mosquitoes of the locality were dissected and, among them, 4.6 per cent. were found infected. After the plasmochin had been administered 3,860 mosquitoes were dissected and only 0.4 per cent. were found to be infected, indicating a great drop in gametocyte carriers among the population. It seems as if the plasmochin treatment sterilized the human carriers, so that mosquitoes could no longer, in biting human beings, pick up and transmit the malaria organism. This particular study was made in a region where practically 100 per cent. of the children have malaria and where the parasite index of adults may be as high as 80 per cent. The anopheline density also is very high. Where

malaria is as prevalent as it is in this case, mosquito dissection furnishes a convenient means of measuring the results of control work. It would require additional and more extensive experiments to show whether mass treatment with plasmochin would be a practical means of malaria control in regions where the application of the usual antimosquito measures is for some reason either difficult or impossible.

Work was also done in connection with the technique of counting malaria parasites in the blood, with the aim of adapting this technique to field work and using it in areas where individuals are lightly infected. Other methods of malaria diagnosis are subject to various errors; and while it cannot be said that the counting of malaria parasites is an entirely accurate method, it has considerable value as a diagnostic technique.

Studies in Southern Nigeria, Africa, offered little evidence of any racial immunity to malaria. The degree of malaria infestation was found to be high at all ages up to middle life. Natives do not acquire complete tolerance to the effect of malaria parasites at least up to middle age.

In the Philippines, the habits and resting places of adult mosquitoes during the daytime were subjected to careful observation, with the aim of improving the technique of catching adult mosquitoes for the purpose of dissection and observation.

In India, in the state of Mysore, a great many mosquito dissections were carried out, but only a small number of mosquitoes were found to be infected with malaria. Such dissections come under the heading of routine laboratory work in connection with the control of malaria.

Hookworm and other intestinal diseases

In the course of the year there were published a number of papers dealing with medicaments for expelling the hookworm. This is a subject on which during the past fifteen years a great deal of research has been done. A number of fairly good vermifuges have been known for some time. But as new knowledge has been acquired, one drug after another has gradually been discarded in favour of something just a little better.

In a paper reviewing this entire subject, it is pointed out that because of the great differences in the structure and physiology of intestinal worms and in their location within the host, no one remedy can remove all types of these parasites. Chemotherapy, to be successful, must be based on a knowledge of the physiology and the life cycle of the various parasites. A recent study of all the substances that have been used in combating such intestinal inhabitants as *Ascaris*, *Trichuris*, *Enterobius*, and the hookworm has shown two of these to be safe and efficient anthelmintics, namely, tetrachlorethylene and hexylresorcinol, the former for uncomplicated hookworm infections, and the latter as an effective remedy also against certain parasites other than the hookworm.

A study was made of the effect of a deficient diet on the susceptibility of dogs and cats to hookworms other than those with which they were normally infected. These experiments suggest the possibility of a close relationship between undernourishment and incidental parasitism even in human beings.

One of the most important prophylactic measures in all hookworm work consists in the building and use of latrines. On this subject much information has been given in the early annual reports of The Rockefeller Foundation. It has been stressed that different kinds of sanitary conveniences are required in different parts of the world, in conformity with local habits, customs, and usages. In recent years considerable attention has been paid to a new device known as the bored-hole latrine, which is easily constructed and which offers certain other definite advantages.

During 1931, field studies of the effectiveness of the bored-hole latrine were conducted in the Philippine Islands; in the Province of Burma, the Madras Presidency, and the State of Mysore, in India; in Ceylon;

and in Egypt. In the United States such studies were a chief feature of the work at the research laboratory at Andalusia, Alabama. An article was published giving full information on bored-hole latrine equipment and construction.

Yaws

Mass treatment of persons with symptoms of yaws has been carried out, but this does not suffice to eradicate the disease. The reservoir of infection occurs among youths up to the age of seventeen, who give a history of yaws but show no signs of the disease. Treatment with salvarsan and similar drugs is causing the gradual disappearance of the disease in certain Polynesian groups. Recent progress in treatment has also been made in Melanesia.

Undulant fever

During 1931 individual cases of undulant fever were studied. In a survey of six communes, selected because of known prevalence of the disease, 12 per cent. of the entire population, or 14 per cent. of persons above the age of fifteen years, were found to have had the disease within the last five to seven years. Laboratory examinations supported epidemiological findings indicating goats and sheep as the main reservoir of infection. The most important means of human contamination seems to be contact with sheep and goats and their excretions. All cultures from human patients as well as from animals have been classified as *Brucella melitensis*. This disease constitutes a serious health hazard to human beings and produces great economic loss through abortion in animals.

Anæmia in Porto Rico

Various kinds of anæmia play an important rôle in the public health problem of Porto Rico. The types of anæmia associated with hookworm disease, malaria, and sprue are relatively common. During 1931 there was undertaken an investigation of selected cases of anæmia as possibly related to direct or indirect dietary deficiency.

In over 150 cases of anæmia associated with hookworm infestation, the rôle played by dietary deficiency and gastro-intestinal changes was clearly brought out. In a hundred cases of anæmia associated with sprue, there was found a close relationship between this disease and certain forms of pernicious anæmia. A careful study was made of the beneficial effect of various substances, especially liver extract, on the blood-forming organs of patients suffering from this form of anæmia.

[Note.—This abstract only deals with the work under the 'International Health division' of the Rockefeller Foundation. But in addition to this there is a long list of medical institutions under the 'Medical Sciences' section which receive grants in aid of specific researches. There are also sections dealing with 'Natural Science', 'Social Science', 'Humanities' the last including assistance to Libraries and Museums, but as these are not matters of strictly medical interest they have not been abstracted here.—*Error, I. M. G.*]

ANNUAL CLINICAL REPORT OF THE GOVERNMENT HOSPITAL FOR WOMEN AND CHILDREN, MADRAS, FOR THE YEAR 1931. MADRAS: PRINTED BY THE SUPERINTENDENT, GOVERNMENT PRESS. PRICE, RS. 4.

This annual report is always full of interest and the present one is doubly so far Lieut.-Col. Hingston has taken the opportunity, before relinquishing his post as superintendent, of giving a brief history of the institution since its inception. He is specially suited for this task as he has been in charge since the year 1914 and he is to be congratulated, for it is clear in the following abstract that the record of progress under his regime has been steady:—

The year 1931 was marked by an increased activity in all the departments of the hospital and was characterized by the fact that the largest number of deliveries

took place during the year since the inception of the hospital in 1844.

In consequence of the large numbers admitted, considerable strain was felt in arranging for accommodation and as unfortunately, owing to the financial crisis, some of the improvements that I had already foreshadowed in the previous report could not be carried out, there was chronic overcrowding in some sections of the hospital, particularly in the gynæcological, post-maternity and ante-natal sections.

This being the last annual clinical report that I shall have the privilege of submitting, I may perhaps be permitted to cast a glance backwards and review the position of the hospital as it is to-day, and to forecast what my hopes are for the future. This hospital was founded in September 1844, and by the end of that year, the total number of confinements was 15. In 1845, the first complete year of its existence, the total number of confinements was 62; in 1861 the number of confinements had just exceeded 1,000 and 30 years later, in 1931, the total number of confinements had just exceeded 2,000. When I took charge of the hospital in 1914, the total number of confinements was 2,251. It is a matter for gratification that the facilities afforded by this hospital have been increasingly utilized by the general public and as has been stated above, in this last year of my official connection, the total number of confinements has exceeded 3,350. This hospital owes a great deal to the enthusiasm and energy displayed by its successive superintendents notably by Harris, Branfoot, Sturmer and Giffard. It was during the time of Branfoot, in the year 1881, that the hospital was shifted to its present site, and the lay-out of this hospital, with its picturesque corridors and well ventilated, airy wards, is due to his sagacity and foresight. The next great change in the construction of the hospital was during the superintendentship of the late Sir Gerald Giffard, who was at the helm of affairs from 1906—1914. During his regime, important additions and alterations were made in the hospital, the most prominent of which were: the construction of the Giffard School, a separate block utilized only for purposes of teaching, fitted with a modern amphitheatre for lectures, rooms for museum specimens, clinical laboratories and research laboratories, a photographic department and residence for men and women students, so that they might have facilities of a stay in the hospital for definite periods for witnessing and conducting obstetric cases. Besides these improvements, the construction of the out-patient and office blocks in the front portion of the hospital, the building up of a wing known as the Branfoot block, wherein the section ward and the puerperal wards are accommodated; the structural alterations in the septic wing of the hospital; the construction of an operation theatre known as the 'Giffard Theatre'; the construction of a spacious Nurses' Quarters on the opposite side of the road in Halliburton's Gardens—these are some of the main additions and improvements for which he was responsible during his regime. It was fortunate that all this building programme was completed before the Great War began, and thus a great impetus was given to this hospital to go ahead with its main function as one of the largest teaching centres in obstetrics and gynæcology for midwives, medical students, and those who propose to take midwifery as a speciality.

During my term of office as superintendent, from 1914 to 1932, an additional theatre was constructed—the 'Hingston Theatre'; improvements were made in several of the wards; the kitchen and laundry were suitably altered and additions were made in the nurses' quarters for accommodation of Sisters, the English educated Indian midwives and the vernacular-trained midwives.

Much as has been the improvement effected during the last 25 years, I feel it my duty to state that this hospital, if it is to maintain its reputation and its status as one of the foremost obstetric centres in the British Empire, should keep pace with modern requirements, and it was with this view that I had already submitted proposals to the Government which I regret very much,

could not be taken up owing to the sudden financial stringency. It is my hope that as soon as the financial situation is relieved, the Government will be able to take up these very necessary improvements for the maintenance of the standards that have been set in this institution. Among the chief of these proposals to which I have referred in previous clinical reports are:—

The improvement of the labour ward with a view to equipping an obstetric operation theatre permanently where all obstetric cases requiring operative interference will be delivered under strict aseptic conditions and to the advantage of the large number of students and post-graduates who are anxious to witness such cases.

The improvement of the septic-delivery ward, which is now in an improvised portion of the hospital, is also urgent in my opinion. Plans have been submitted with a view to delivery of 'suspect' cases in separate cubicles and the obvious septic cases in other cubicles. I consider this is very essential to prevent any possibilities of cross-infection and to ensure the highest standards of aseptic midwifery to the women who seek relief at our hands.

The construction of an ante-natal ward and a suitable ante-natal out-patients' clinic, and a separate children's department, is also a necessity that should be taken up as early as possible. Within the last three years, we have organized more definitely an ante-natal out-patient clinic which is increasingly popular and which is in charge of a separate officer of the grade of a Civil Surgeon. The children's out-patient department has increased in utility, and I think it will soon be necessary to separate the infant welfare department from the children's clinic, and to concentrate more and more upon the physiological requirements of the infant through the infant welfare department.

The venereal disease clinic attached to the ante-natal clinic has also increased in its utility, while the out-patient gynaecological clinic is showing how much it can draw the patients from different parts of the country. It must be recognized that this hospital is not a hospital catering to the needs of the citizens of Madras, but is a provincial concern, and the majority of our serious cases, particularly gynaecological, and some obstetric cases, are drawn from practically every district of the Presidency and from the neighbouring Indian States. A hospital catering for the needs of such a large and diverse population should therefore be looked upon as a provincial concern, of utility to the citizens of the Presidency as a whole, and not to those of Madras in particular.

Within the last three years again, we have opened a Mothercraft Department which is now in charge of a trained Sister and this department has served not merely to look after those children who are entrusted to the care of the department, but to diffuse proper knowledge and information to many mothers in Madras who have freely resorted to the department for advice with regard to infant feeding and infant care in general. The department is also training a number of midwives in mothercraft work, so that when these midwives pass out, and go to the mofussil, they may carry the lighted lamp to many a dim corner where primitive ideas of infant feeding and infant care are now existent. All these activities have necessarily their own part to play in increasing the financial burden, but one may state with confidence that the returns for such expenditure as may have to be spent on the maintenance of an institution such as this, are immeasurably greater not merely in the health and safety of the mothers but also in the better conditions of life of the children and what is far more important, in the training of so many competent midwives and obstetricians, who I trust will disseminate this knowledge in their practice throughout the different parts of this Presidency and of India, in general. It has been a very gratifying feature for me to note that Indian practitioners are taking more largely to obstetrics and gynaecology and there has been a steady and an increasing stream of qualified practitioners

from all parts of India, from Burma, from Straits Settlements, Sumatra, Java and from several other parts of the Far East, for a post-graduate training in this hospital. The need for organizing such post-graduate training is great, and while every impetus has been given so far, I trust that in the future, a more systematized scheme of post-graduate training will be possible, when we have instituted our diploma of Licentiate in Gynaecology and Obstetrics, for which proposals have been submitted to the Government. The University, in 1927, instituted a Diploma in Gynaecology and Obstetrics, and I am glad to state that so far six graduates of the University have taken the Diploma. The Diploma in Gynaecology and Obstetrics, requires a course of study of one year, six months of which at least should have been spent as a House Surgeon in one of the recognized maternity institutions in the City, wherein the candidate would have conducted at least six cases of obstetric operative delivery under supervision; later a six months' training in the wards of this hospital is compulsory. I have submitted proposals to the Surgeon-General for the institution of a licence for those who are not in a position to take the longer course of a year, and it is contemplated that this licence may be of a six months' duration and that the course will be as practical as possible, so that the candidates who get through this course will have a very fair idea of the practice of obstetrics. I hope that in the future, the institution will be even more largely utilized for the post-graduate training of midwives, for I feel that it is no use our training midwives and sending them to the different parts of the country, if they are not given periodical post-graduate training, so that they may keep themselves up to the mark, and I can think of no institution which affords the same facilities for a short post-graduate training of three months for these midwives.

In-patients.

During the year 1931, 9,106 patients were treated in this hospital, of whom 947 were children and 8,159 were women and the following table gives the particulars regarding these admissions:—

	Admissions	Deaths
(1) Ante-natal cases ..	2,144	26
(2) Maternity cases (cases delivered in the hospital, or admitted within 24 hours after delivery at home) ..	3,389	84
(3) Post-maternity cases (delivered at home and admitted into hospital 24 hours after delivery) ..	228	28
(4) Children's section ..	947	188
(5) Gynaecological cases ..	1,360	37
(6) General diseases treated ..	1,038	43
TOTAL ..	9,106	406

The total number of deliveries for the year under report was 3,389, the total number of children born being 3,160, and the number of abortions being 270.

The total number of children delivered for the 3,119 women who were confined (exclusive of abortions) was 3,160. It will be noticed that the percentage of live-births was 91.04, inclusive of the macerated foetuses, and 93.8 exclusive of macerated foetuses. The greater proportion of still-births as compared with the rate of maternity institutions in the West is due to the fact that a heavy incidence of still-birth rate results in what are known as complex labours, that is, in those patients who come into labour with some complication of pregnancy, generally one of the tropical diseases. It is in these cases that prematurity is one cause of still-birth, and the complication itself the other main cause; and that this is so will be obvious from a study of the statement given above from which it will be

found that in the complex labours there were 73 macerated fetuses and 113 still-births.

It is in this class of labour also that neo-natal mortality is the largest and in the year under report, 97 children died among the complex labours. It is a great problem for the obstetrician how to avoid these complications in pregnancy in tropical countries like India, and one must confess that while ante-natal hygiene and ante-natal treatment will undoubtedly, if conducted on proper and sound lines, and pushed to the logical extent, mitigate the severity of these complications, the real problem will only be tackled when better hygienic facilities are available for the whole community. The incidence of malaria, typhoid, dysentery, influenza, the infectious fevers and pneumonias, is yet too great in the general community as well as in pregnant women to warrant the hope that the heavy morbidity and mortality both to mothers and children, can be reduced to any reasonable proportion, unless a much greater leeway is made with the general hygiene of the population at large. It does not however mean that ante-natal work should not be pushed forward with greater vigour than is apparently the case at present in the City as a whole. It only shows that brilliant or surprising results from ante-natal work alone cannot be expected unless the general hygiene of the population *pari passu* is improved.

An analysis of the causes of foetal mortality among the natural labours make it clear that the large majority of them were due to unavoidable causes so far as the hospital is concerned. There were 67 cases of tedious labour, with one macerated foetus, and 294 cases of laborious labour. Under 'laborious labour' the application of forceps was performed in 257 cases, while there were 4 cases of a symphysiotomy and 12 cases of Cæsarean section. Internal podalic version was performed in cephalic presentations in 15 cases, with 4 still-births, and no death to the mother. We may reiterate our experience that the delivery of a foetus as a breech presentation in those cases where, particularly in multiparæ, the head does not engage owing to an imperfect flexion or malposition, is far safer than the application of forceps, both to the mother and to the child.

There was one case of secondary abdominal pregnancy.

The statement below furnishes the details of complex labours. It will be noticed from this statement that there were—

	Cases
Plural births	41
Eclampsia	67
Accidental hæmorrhage	31
Placenta prævia	22
Rupture of uterus	8
Descent of funis	6
Post-partum hæmorrhage	48
Hydramnios	6
Foetal malformations	9
Albuminuria	100
Anæmia	115
Other complications	315
TOTAL	768

Puerperal eclampsia

There were 80 cases of eclampsia admitted for treatment during the year under report, of whom 14 died, giving a mortality of 17.50 per cent. Of the 80 cases, 43 were primiparæ and 37 multiparæ. During the year under report, there has been a change in the treatment of puerperal eclampsia. We still hold that the reduction of the blood pressure is one of the important things to look to, and we have attempted this by the administration of parathermone and calcium. Blood analysis has been made biochemically of a number of cases of eclampsia and a report on this condition as well as on the lines of treatment that are adopted is being submitted in a separate paper.

The details of the morbidity statement furnished makes it evident that the morbidity rates in tropical

countries must necessarily be much higher than in European countries. As a matter of fact, the very large number of cases of morbidity, whether it be in natural labours or in tedious and complex labours, are necessarily due not to the incidence of sepsis but to the various tropical complications which, as has been stated already, are far too frequent in pregnant women in tropical countries. Any useful comparison therefore is not possible as regards the standard of morbidity in maternity institutions in tropics and elsewhere.

In the gynæcological section of the hospital, 1,360 cases were admitted. We have during the last year under report, treated a very large number of cases of cancer of the cervix, the body of the uterus, and the vagina with radium therapy. Articles on this subject have been published by some of the members of the staff in medical journals and a concise report of the treatment of cancer with radium and of the results thereof will be published later. It is unfortunate that the large majority of cases come at a time when any possibility of operative treatment does not arise before or after radium treatment; and although radium has undoubtedly a very great effect upon improving the general health of the patient, relieving her of her symptoms notably pain and hæmorrhage and destroying large fungating growths, it cannot be said that the results have at all been satisfactory, taking a 3 or 5 year period test of survival into consideration. I can only hope that, with much better propaganda and a keener appreciation by the practitioners up-country of the early signs of cancer, we will be able to get into touch with these cases at a much earlier stage when either radium therapy by itself, or combined with operation, would prove much more satisfactory.

ANNUAL REPORT OF THE MEDICAL OFFICER OF HEALTH, OF COLOMBO, 1931. PRINTED AT THE MUNICIPAL PRINTING OFFICE, CEYLON.

We have on previous occasions commented on the excellence of these reports, which are well written, well printed and produced, and illustrated by good photographs and diagrams. The present one is of the same high standard. We believe that tourists have frequently noted the cleanliness of Ceylon; and this may be taken as an index of the care bestowed on less obvious matters of sanitation. Colombo has a population (1931) of 234,155. The birth rate for 1931 was 30.8, the death rate 25.1; the infantile mortality and maternal mortality rates 172 and 24.8 per 1,000 births. The chief point of note is the comparative absence of ordinary tropical diseases as causes of mortality, and the high incidence of phthisis (2.22 per 1,000), pneumonia (3.18 per 1,000) and diarrhœa and enteritis (1.56). The mortality from respiratory diseases is usually an index of bad housing and overcrowding. Parts of Colombo have over 150 persons per acre, and the average is 34 per acre. This is less than many of our Indian towns.

A very good description is given of the maternity and child welfare work. This is now on an excellent basis. The staff consists of one special whole-time medical officer, one Superintendent of Health Nurses, twenty-one Health Nurses and sixteen Midwives. Photographs of the dispensaries and welfare centres are given. The fact that the infantile mortality rate has diminished from 410 per 1,000 births in 1903 to 172 in 1931 is some testimony of what has been done. The maternal mortality, however, has not decreased in the same manner. In 1930, a Midwives' Ordinance was passed, which apparently insists on compulsory registration of every midwife; and such registration apparently depends on some form of training at least. The effect of this ordinance may emerge as time goes on, but cannot yet be judged.

Ever since 1913 plague has been endemic in Colombo, particularly in certain of the dock areas. There is a constant danger of exportation to the interior of the Island and indeed this has happened on several

occasions. Dr. Hirst's views on this are well known; i.e., that the beginning of plague in Colombo in 1913 was due to the importation and establishment of colonies of *Xenopsylla cheopis*. His views have been supported to a large extent by the investigations in Madras Presidency, of Lieut.-Col. King and his collaborators. In 1931 there were in Colombo 47 cases of human plague and 45 deaths. The earliest case was diagnosed as cerebral malaria and the second case was reported as primary pneumonic plague. No other pneumonic cases occurred however but only septicaemic and bubonic cases.

The phthisis problem was fully discussed in the previous report and is not revised again. It is in Colombo as in other towns in the tropics the health problem *par excellence*.

The report is well got up, easily read and informative.

Correspondence

VACCINATION AGAINST SMALLPOX

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I shall be greatly obliged if you kindly give your opinion regarding the following points in connection with vaccination against smallpox.

Is it possible to fix any dose of the lymph to be inoculated?

The manufacturers of the lymph direct that a certain number of persons should be inoculated with the amount contained in the tube. We have recently found that more than 16 persons can be inoculated, apparently successfully, with a tube of lymph which was meant, on the manufacturers' word, only for 4 persons. There was the typical vesicle, pustule, and all that. Only a pin-point of lymph was used in most of these cases, and the scratches consisted only of one point.

Is the object of the vaccination simply to produce a sensitization of the system through the skin, or to give a definite dose, as in the case of ordinary vaccines, where so many millions of bacteria are introduced into the system?

If the object of vaccination be to sensitize the system through the skin, then why it is insisted that more than two places must be scratched in cases of primary vaccination, where the system is more likely to react, than in the case of the revaccinated, where the failure of some of the scratches may be expected?

If any particular dosage is advisable, then why is not stress laid on the length, breadth, and number of the scratches?

Yours, etc.,

A. B. MUKHERJI, L.M.P.

NUTANGUNJ,

BURDWAN,

22nd February, 1933.

[Note.—We referred the questions raised by Dr. Mukherji to Lieutenant-Colonel A. D. Stewart, I.M.S., Director, All-India Institute of Hygiene and Public Health, Calcutta, who kindly supplied the following information on the subject:—

'The questions put by your correspondent are of some importance and may interest the profession at large, especially in view of some of the recent vaccination orders by the Ministry of Health of England and Wales.

After the discovery of Jennerian vaccination against smallpox, the Germans took up the matter with characteristic thoroughness. They first demonstrated that the number of cases of smallpox developing after vaccination were very few indeed when there was evidence of four points of original vaccination, more numerous when there were three, and proportionately still more numerous when there were two, one, and none at all. They further showed that the protection was proportional

to the vesicular scar area (not necessarily the whole scar area); the typical vesicular area being the foveal spot with a central spot of umbilication. They finally showed that the maximum amount of protection was procured when at the primary vaccination a certain minimum amount of vesicular area was produced. This was found to be half a square inch. When less than this area was produced, the protection was not maximal, but a vesicular area in excess of this did not increase the protection given. Efficient vaccination was then defined as resulting in "the maximum amount of protection at one vaccination, with the minimum amount of trauma". This last condition was satisfied if the vesicular area was spaced over four insertions in the form of simple linear incisions about half an inch long. To obtain fully efficient primary vaccination, therefore, a certain amount of lymph, sufficient for the four incisions, is necessary. It is this amount of lymph which is referred to as being necessary for one person and which forms the basis of calculation and instruction for use by vaccine departments. A certain amount of protection can be given with one insertion, but it is not maximal and lasts for a shorter period. The question whether this maximal protection is always necessary has been raised by the Andrewes and the Rolleston commissions on post-vaccinal encephalitis (see *Indian Medical Gazette*, August 1930, p. 459 for a good résumé of this subject). "One-point" vaccination with diluted lymph is now recommended in many cases, with revaccination at shorter intervals. Post-vaccinal encephalitis about the year 1922 was more frequent in Holland and England than elsewhere and it was found to occur practically only in primary vaccinations in older children (3 to 12 years) and practically not at all in infancy. One doubtful case only has been reported in India (see *Indian Medical Gazette*, August 1930, p. 443). Infancy is therefore the best period for primary vaccination and in India I see no reason at present for not trying to get the full efficient vaccination with four points.

Cross-hatching methods of vaccination should be absolutely forbidden of course (it is yet distressingly common). Simple linear incisions are satisfactory or the circular drill, used carefully, inflicts little damage.

I think these observations may meet your correspondent's queries.—EDITOR, *I. M. G.*

Service Notes

APPOINTMENTS AND TRANSFERS

THE services of Lieutenant-Colonel T. L. Bomford are replaced at the disposal of the Government of India, Army Department, with effect from the 26th February, 1933, on the expiry of the leave granted to him.

Lieutenant-Colonel P. F. Gow, D.S.O., officiating Second Professor of Midwifery, Medical College, Calcutta, is appointed as Professor of Midwifery of the College and Obstetric Physician and Surgeon, Medical College Hospitals, *vice* Lieutenant-Colonel V. B. Green Armytage, granted leave.

Lieutenant-Colonel W. J. Powell, C.I.E., Inspector-General of Prisons, Central Provinces, is appointed to officiate as Inspector-General of Civil Hospitals, Central Provinces, during the absence of Colonel Wilson on leave.

Major B. G. Mallya is appointed temporarily as Superintendent, Campbell Medical School and Hospital, Calcutta, with effect from the 9th February, 1933.

Major L. K. Ledger, an Agency Surgeon on return from leave, is posted as Agency Surgeon, Gilgit, with effect from the forenoon of 15th October, 1932.

The services of the undermentioned officers are placed permanently at the disposal of the Government of the Central Provinces, with effect from the dates shown against their names:—

Major J. M. R. Hennessy, 2nd September, 1931.

Major R. A. Logan, 19th April, 1932.

The services of Major S. L. Patney, are placed permanently at the disposal of the Government of Bengal, with effect from the 11th July, 1930, for employment in the Bengal Jail Department.

The services of Major S. D. S. Greval, an officer of the Medical Research Department, are placed temporarily at the disposal of the Government of Bombay for appointment as officiating Assistant Director, Haffkine Institute, Bombay, with effect from the 14th November, 1932.

The services of Captain H. S. Waters are placed temporarily at the disposal of the Government of Bombay, with effect from the forenoon of the 5th December, 1932.

The services of Captain J. J. Beausang are replaced at the disposal of His Excellency the Commander-in-Chief in India, with effect from the forenoon of the 4th February, 1933.

Captain G. F. Taylor, an Officiating Agency Surgeon, on return from leave, is posted as Medical Officer and *ex-officio* Vice-Consul, Sistan, with effect from the forenoon of the 4th February, 1933.

The undermentioned officer is confirmed in the rank of Captain:—

Captain (provl.) F. H. A. L. Davidson.

PROMOTIONS

Lieutenant-Colonel to be Colonel

Brevet-Colonel E. C. Hodgson, D.S.O., K.N.P. Dated 23rd January, 1933, with seniority 30th July, 1927.

Majors to be Lieutenant-Colonels

N. K. Bal, M.C. Dated 25th January, 1933.

H. S. G. Haji, M.C. Dated 25th January, 1933.

S. S. Sokhey. Dated 26th January, 1933.

J. Findlay. Dated 26th January, 1933.

W. C. Spackman. Dated 26th January, 1933.

J. C. De. Dated 26th January, 1933.

C. H. P. Allen. Dated 26th January, 1933.

R. V. Martin. Dated 26th January, 1933.

The promotion of Major J. J. Rooney to the rank of Major is antedated to the 22nd January, 1929.

Captain to be Major

J. A. W. Edden. Dated 20th January, 1933.

The provisional promotion to the rank of Captain of the undermentioned officer is confirmed:—

Captain (on prob.) (provl.) Sangham Lal.

Lieutenant to be Captain (provl.)

G. K. Graham. Dated 3rd February, 1933.

The seniority of Lieutenant (on prob.) J. W. Bowden is antedated to 20th October, 1931.

LEAVE

Colonel H. R. Nutt, Inspector-General of Civil Hospitals, United Provinces, is granted leave on average pay for 7 months, and 5 days, with effect from the 30th March, 1933.

Colonel F. E. Wilson, Inspector-General of Civil Hospitals, Central Provinces, is granted leave on average pay for 3 months and 16 days combined with leave on half average pay for 4 months and 15 days, with effect from the 7th March, 1933, or subsequent date from which he may avail himself of it.

Lieutenant-Colonel E. W. O'G. Kirwan, Professor of Ophthalmic Surgery, Medical College, Calcutta, and Ophthalmic Surgeon, Medical College Hospitals, is granted leave for 8 months, with effect from the 25th February, 1933, or date of availing.

Lieutenant-Colonel H. Hingston, Surgeon to His Excellency the Governor of Bengal, is granted leave for 28 months from the 9th March, 1933, or any subsequent date of availing.

Lieutenant-Colonel V. B. Green-Armytage, Professor of Midwifery, Medical College, Calcutta, is granted leave for 2 years and 4 months from 27th March, 1933.

or from any subsequent date on which he may be relieved.

Lieutenant-Colonel J. B. Lapsley, M.C., Officer in charge Medical Store Depot, Lahore Cantonment, is granted 12 months combined leave ex-India (the first two months being privilege leave), with effect from the 5th June, 1933, or date of availing.

Lieutenant-Colonel G. G. Hirst, Officer in charge Medical Store Depot, Madras, is granted privilege leave from the 1st April to 31st May, 1933, combined with leave on private affairs ex-India from the 1st June, 1933, to 23rd January, 1934, pending retirement.

Major A. H. Harty is granted 8 months' leave, with effect from the 1st March, 1933, or subsequent date of relief.

Major S. N. Mukherji, Superintendent, Campbell Medical School and Hospital, Calcutta, is allowed leave for 1 month, with effect from the 27th January, 1933.

Major H. Williamson, O.B.E., an Agency Surgeon, is granted under Fundamental Rules, leave for 1 month, with effect from 16th January, 1933.

Major W. P. Hogg, D.S.O., M.C., an Agency Surgeon, is granted leave for 6 months, with effect from the forenoon of 15th October, 1932.

RETIREMENT

Lieutenant-Colonel M. R. C. MacWatters, retires with effect from 4th January, 1933.

Notes

EPHEDROL

THIS new cold cure, which is put up in a very convenient form, has a composition as follows:—

R. Ephedrine	1 per cent.
Camphor.	
Menthol aa	2 per cent.
Aromatic oil	q.s.
Neutral oily base to 100 parts.			

The chief difficulty which has attended the use of such solutions in the past has been the trouble encountered by the patient using an atomiser which is expensive, and quickly gets out of order. Ointments in tubes are unsatisfactory as the medicament does not penetrate far enough into the nasal passages to be of much use.

Ephedrol is packed in one ounce bottles with a special orifice designed to fit the nostril. The flat-shaped bottle is ideal for carrying about, and enables the patient to use it at the first symptoms of nasal catarrh or hay fever.

KODAK LTD.

THE value of the cinema as an aid to medical education and as a medium in health propaganda is daily becoming more apparent. Kodak Ltd. are therefore doing all those interested in health propaganda, as well as those with a more general interest in the cinema, a singular service in arranging for the employment of a cinema expert with a world-wide reputation to be available in India. Mr. G. Quiribet has just arrived in India to join the staff of Kodak Ltd. in Bombay.

Mr. Quiribet's name is already famous in two continents, where he has assisted in the production of a number of pictures. He has seen the cinema industry evolve from small, obscure beginnings to one of the first magnitude, his experience dating back to 1906, when he was in charge of one of the laboratories of Pathé Frères Producing Co. Later he went to England and after the war realising that America was introducing revolutionary improvements and rapidly perfecting film

technique, he went over and worked in two of the largest American studios.

It is hoped that Mr. Quiribet's valuable experience will aid the cinema industry in India, and lead to the production of pictures of educative and artistic value equal to those which are now imported from other countries.

UPPER FIXATION FORCEPS

By D. PRIESTLEY SMITH, M.B., M.R.C.S.

These forceps are for fixing the eye in cataract extraction. One foot is placed on the upper limbus and the other 5 or 6 mm. higher up on the globe. They

are then closed. This gathers up the intervening conjunctiva to the limbus, where it forms a fold or pleat held at its base in the forceps. This affords very good fixation. The corneo-scleral section is now made forthwith, the knife cutting out immediately behind the feet of the forceps, i.e., through the posterior layer of the conjunctival fold. This procedure makes a good conjunctival flap. The forceps are made by Down Bros. Ltd., London.

HALIVEROL

VITAMIN THERAPY IN TUBERCULOSIS

THERE appears to be an increasing interest in the possibility of favourably influencing tuberculosis by vitamin-D therapy, and growing opinion that adequate doses of vitamin D are of value in promoting calcification of tuberculous lesions. The use of vitamin D for this purpose has an obvious rationale.

The calcification of the tubercle has long been considered as one of the end results of the constructive forces in the healing of tuberculous infection in tissue. Obviously, therefore, therapeutic measures which tend to increase calcification might be regarded as logical.

Crimm (*American Review of Tuberculosis*, January-June, 1931) reported that 'the use of activated ergosterol in therapeutic doses increased the absorption of calcium and inorganic phosphorus', and stated, in relation to the use of irradiated ergosterol in the treatment of pulmonary tuberculosis, 'In the end it may prove to be more effective in the acute disease than sunshine is in chronic pulmonary tuberculosis'.

The above and other reports indicate a growing interest in vitamin-D therapy in the treatment of pulmonary tuberculosis.

It is therefore apparent that if cod-liver oil and irradiated ergosterol have a beneficial effect in this condition that other substances which are richer in vitamin content may be expected to give equally good, if not better, results. Haliverol (Parke, Davis & Co.) for example is said to contain 60 and 250 times as much vitamin A and D, respectively, as does an equal quantity of cod-liver oil and should be particularly useful.

Gordon and Flanders (*American Review of Tuberculosis*, 1931) have emphasized the importance of maintaining adequate vitamin-A intake in tuberculous patients. The many physicians who have had long-continued and firm faith in cod-liver oil in the treatment of tuberculous patients, because of it affording both the fat-soluble vitamins, will welcome the advent of Haliverol. Many tuberculous patients have a capricious appetite and cod-liver oil is obnoxious to them. Others have a limited digestive capacity for fats. While fat is an essential part of the diet for the tuberculous patient, this can be more advantageously provided by

butler and cream. The chief justification for the use of cod-liver oil in tuberculous patients is as a vehicle for the fat-soluble vitamins. This can now be provided in larger doses and much more conveniently in Haliverol.

In addition to Haliverol in liquid form convenient capsules are now available; they are easily swallowed and are of 3 minims capacity, i.e., they contain the equivalent of three teaspoonfuls of the finest cod-liver oil in vitamin A and 3 minims of irradiated ergosterol 250 D in vitamin D. The standard package contains 25 such capsules, and for small children and others unable to swallow a capsule the liquid is available in vials of 5 c.cm. and 50 c.cm. in cartons, with convenient

droppers included—9 drops from which equal the contents of a capsule.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

As misunderstanding still appears to exist, we should like to point out again to our readers and advertisers that the "*Indian Medical Gazette*" is owned and published by Thacker's Press & Directories, Ltd. Hitherto, Thacker, Spink & Co., now in liquidation, have been the selling agents; this work is now being undertaken by Thacker's Medical Book Dept., Box No. 54, Calcutta.

SOME BYPATHS OF ORTHOPÆDIC SURGERY

By W. L. HARNETT, M.A., M.D. (Cantab.),
F.R.C.S. (Eng.)

LIEUTENANT-COLONEL, I.M.S.

*Professor of Surgery, Medical College, Calcutta, and
Surgeon to the College Hospitals*

No country offers a wider field for the orthopædic surgeon than India. Fractures and dislocations occurring in villages far from medical aid are undiagnosed and are treated by the most primitive methods, with the result that months afterwards surgeons see them with the most astonishing deformities, for the treatment of which the textbooks give one little help. Inflamed joints are allowed to lie for months in the position most comfortable to the patient, who presents himself with extreme degrees of flexion or abduction, such as are never seen in Europe and which tax all one's resources to rectify within a reasonable time and obtain a good functional result. These are the common cases, but amongst them the rarer orthopædic conditions will be met with from time to time if one is on the look-out and it is with some of these that this paper deals.

Little's disease

Case I.—The patient, admitted to the Prince of Wales' Hospital on 18th December, 1930, was a Bengali boy, aged 8. The parents were healthy and he was the fourth child; the first child was born dead at 7 months, the second was a still-birth at full term, the third, also a full-term child, died a few hours after birth, and the patient had been a full-term child. All the labours were prolonged, but there was no history of instrumentation; all the labours were conducted by *daïs*. The parents denied the possibility of syphilitic infection. From birth it was noticed that the child kept his hands and legs crossed, but the deformities of the legs were not noticed until he was about four months old and those of the hands at a later date. It was also stated that there was sometimes defective control of the anal sphincter. The child began to walk later than usual and always with difficulty. Mentally the boy has always been intelligent and in advance of his years, but of a somewhat unstable temperament. On examination he was found to be well developed but rather thin. The thoracic and abdominal organs were healthy, the urine and faeces were normal and there was no fever. Both legs were adducted and internally rotated at the hip joints, and both feet were in marked equino-varus with adduction of the anterior parts of the feet; all these changes were more marked on the right side than on the left, and callosities had formed over the talus on both sides from walking on the outer borders of the feet. Spasticity of the tibialis anticus and tibialis posticus muscles was very marked, so that eversion of the feet was impossible and any attempt to produce it forcibly set up spasm and pain. The knee joints were held in the extended position and could be easily flexed, but extension was resisted by spasticity of the flexor muscles. There was a normal range of unresisted flexion and extension at the hip joints, but abduction was checked by spasm of the adductors; all these changes were more marked on the right

side. In walking there was marked adduction of the thighs, producing a tendency to cross-legged gait which the patient resisted by an effort of will, whilst the internal rotation of the feet necessitated the legs being held wide apart. The joints of the upper limbs had a normal range of movement, except for pronation of the right forearm, which could not be corrected. By gentle steady pressure the spastic muscles of the lower limb could be stretched until the foot was in a normal position, but the manœuvre was apt to set up clonic spasms and the deformity reappeared as soon as the pressure was relaxed. The knee jerks were exaggerated and ankle clonus was present on the right side, but patellar clonus was not present. Sensation was normal and there was no muscular wasting. The boy was intelligent and very anxious to overcome his disability, but was of an excitable nervous disposition. The Wassermann reaction was negative.

This disease is a lesion of the upper motor neurone due to disease or injury of the cerebral motor centres, resulting in a condition of muscle hypertonicity with exaggerated reflexes. It is not therefore strictly a paralysis, but a hypertonicity varying from slight muscular irritability to a condition of spastic rigidity which renders the limbs useless, not from loss of muscular power but from excess of contraction. According to its distribution it may be a monoplegia, diplegia, hemiplegia or paraplegia.

The causes may be ante-natal, natal, or post-natal:—

Ante-natal cases are due to errors in development and syphilis is an occasional factor.

Natal cases include the majority. Intracranial hæmorrhage is caused by trauma to the head during prolonged labour, forceps delivery or prolonged asphyxia at birth, leading to sclerosis, cysts, atrophy and porencephaly affecting the cortex, corpus striatum and basal ganglia.

Post-natal cases are mostly due to chronic meningitis, encephalitis and polio-encephalitis, or thrombosis due to marasmic conditions or to syphilis.

However it be caused, the essential pathology is a lesion of the motor area with atrophy of the affected portion and degeneration of the pyramidal tracts and two-thirds of the cases occur during the first three years of life.

The clinical signs will of course vary with the type of case; but a stiff irritable condition of the muscles is common to all, any effect at control of the limb or the execution of a special movement being apt to throw them into increased spasm. Standing, walking and all movements are executed clumsily and uncertainly, the impression produced being that the muscles have taken charge and that the patient is making efforts of volition to control them, which is exactly what is taking place. The limbs tend to assume certain positions determined by the relative strength of the opposing groups of muscles, the foot is held in equinus with often an element of varus or valgus, the knee is flexed, and the hip is flexed, internally rotated, and adducted. If both limbs are affected by adductor spasm the patient will cross one leg over the other when an attempt

is made to walk (scissors gait). In the upper limb the shoulder is held internally rotated and adducted with the elbow flexed, the forearm pronated and the fingers flexed. At first these deformities can be corrected by manipulation, though the sustained pressure often sends the whole limb into generalized spasms, later adaptive muscular shortening occurs and the deformities cannot be corrected, an important point to be considered in determining the line of treatment. Increased knee jerk, ankle clonus and other signs of loss of control by the upper motor neurone are present in varying degree, according to the severity of the case, choreic and athetoid movements occur in the paralysed limbs in the worst cases. In the majority of cases some degree of mental impairment exists, varying from practical idiocy to a defect which may be so slight that it is only manifested as the child grows older and becomes sensible of the limitations imposed by his condition. Mental deficiency to such a degree that the child is unable to understand and obey orders is an absolute bar to surgical treatment, since the child will be unable to co-operate in the all-important re-education of the muscles.

The case described above was a good example of a mild type of the disease. The attitude of the feet was characteristic, but the knee joint position was atypical in being held in extension rather than in flexion. The hip showed adduction deformity sufficiently severe to cause a mild degree of cross-legged progression, but no flexion. The upper limbs were normal except for spasticity of the pronators of the right forearm. The child was very bright mentally and anxious to improve, so that he was as favourable a subject for treatment as one would be likely to meet. These cases are not at all uncommon in India, no matter for surprise when one considers the ætiology, though usually they suffer from such a degree of mental impairment that their condition is hopeless. When this is not the case, as in the present instance, a great deal can be done by surgical treatment. The lines of treatment fall into two groups of methods:—

A. Non-operative treatment

Muscle re-education is an essential part of the after-treatment of operated cases, though by itself it is not enough except in the mildest cases. It aims at teaching the patient to use the weaker muscles, the instructor carrying the movements a little beyond the extreme range of voluntary movement by gentle stretching, the effect of which is a gradual increase in the range. Non-weight-bearing exercises are of course preferable and rhythmical movements such as drill are of great value. Only a minority of cases can be handled by these methods alone. Where marked muscular resistance is encountered in performing the exercises operative measures are desirable if the intelligence of the patient is such that post-operative

muscle re-education seems practicable. Massage is contra-indicated in this condition, as it increases muscular tone, and intermittent stretching of the contracted muscles tends to make them stronger and the muscular balance worse than it was originally. Continuous stretching on the other hand is good treatment, provided that it does not set up spasm which means that it must not be increased beyond the position of easy tolerance.

B. Operative treatment

This should not be attempted before the age of 5 or 6 years and then only in children with sufficient intelligence to understand and obey orders. The operations employed may be classified as follows:—

1. Operations on the peripheral nerves

(a) *Foerster's operation of intraspinal section of the posterior spinal nerve roots proximal to their ganglia.*—It was hoped that this operation by cutting the afferent paths to the cord would check the hyper-activity of the muscles deprived of the controlling influence normally exercised by the pyramidal tracts. The results of this severe operation were disappointing, as it was found that voluntary control was diminished no less than reflex spasticity and the operation has now been abandoned in favour of simpler methods.

(b) *Sympathetic ramisection.*—Hunter believed that muscle tone was largely under the influence of the sympathetic system and that the operation of ramisection devised by him and Royle would abolish spasm whilst leaving voluntary control intact. That some degree of success has been attained by this operation is undeniable, but a committee of orthopædic surgeons in London who examined the end-results of a series of cases operated upon by Royle himself reported that the results were not permanent and the operation is not likely to come into general use, though it has blazed the trail for operations on the sympathetic system in other conditions which do not concern us here, but which appear to be opening up a new and promising branch of neuro-surgery.

(c) *Stöffel's operation* interrupts the reflex arc on the motor side. By studying the intraneural topography of the large nerve trunks, Stöffel demonstrated that the various tracts run independently for a considerable distance and that the position of any bundle in a large nerve at a given level is remarkably constant. He was therefore able to pick out the nerve supply to any required muscle group and destroy as much or as little as he wished in any individual case. This relaxed the spasm in a certain number of muscle fibres in each muscle by cutting out part of its nerve supply. Stöffel's operation is not now used in its original form, surgeons preferring to follow the nerve down till the branches to the individual muscles can be traced. The whole or a portion of the nerve

supply to a given muscle is resected and in this form the operation has become firmly established, the effect is lasting and there is no tendency to recurrence. Its most successful application is in the ease of the adductor spasm by resection of the anterior branch of the obturator nerve or in severe cases of the whole nerve. It can also be applied to the sciatic nerve for the treatment of knee flexion, to the tibial and superficial peroneal nerves for pes equinus and lateral deformities of the foot and to the median nerve for the correction of contracture of the pronator radii teres and of the flexors of the fingers.

2. Operations on muscles and tendons

These include tenotomy, myotomy, tendon lengthening, tendon transplantation and shifting attachments of muscles. These are the oldest forms of treatment and are of great value, but all have the drawback that they do not attack the underlying causes of the condition, the diffuse irregular efferent nerve impulses which produce the spasm, so that recurrence of the deformity is very likely to occur. It must also be borne in mind that spastic muscles bear stretching very badly, the attempt to do so often causing marked general disturbance, an increase in the nervous symptoms and even convulsions, so that it is never wise to put up limbs in a more corrected position than the gain by operation easily permits. Nevertheless much can be done by these comparatively simple methods and in general it may be said that whilst the milder cases will yield to peripheral operations, the more severe call for Stöffel's operations on the motor nerves supplemented by peripheral tenotomies, etc., to correct any real contractures which may have developed. In any case the subsequent treatment by muscle re-education is to be regarded as the most important part of the regime, to which operation merely removes the obstacles.

The case described was treated as follows:—

1st stage.—Manipulation under general anaesthesia. All the deformities disappeared as soon as the patient was under the anaesthetic, and no fixed contractures were found; he was put up in plaster of Paris with the thighs fairly widely separated. This treatment caused great pain and spasm and for many days he had to be kept under the influence of sedatives. As soon as the plaster splint was cut off, the deformities all reappeared, not the slightest benefit having resulted.

2nd stage.—One month later, Stöffel's operation on the anterior branch of the obturator nerve of the right side.

3rd stage.—Two weeks later, Stöffel's operation on the left obturator. The benefit derived from these operations very soon became apparent and after a few months of exercises designed to stretch the remaining adductor muscles the boy was able to abduct his thighs freely, though not yet to the normal degree.

4th stage.—Six months later, Stöffel's operation on the right posterior tibial nerve. A long incision was made directly downwards in the midline from the centre of the popliteal space. The tibial nerve was identified and followed down by splitting the gastrocnemius and soleus muscles. By electrical stimulation the nerves to the medial and lateral heads of the gastrocnemius and that to the tibialis posterior were identified and divided, the branch to the flexor longus hallucis which arose in common with the branch to the tibialis posterior being also divided. The dissection necessary is a somewhat formidable proceeding, but the use of a tourniquet much facilitates the operation. The writer then went on long leave out of India and the patient was discharged one month later; the note on discharge records that the wound was completely healed, that there was good abduction, the cross-legged progression had completely disappeared and that the spasm of the leg muscles was much less.

The patient was seen again one year later and the improvement in his condition was most gratifying. The knee jerks were still exaggerated, but the ankle clonus had disappeared. There was still slight flexor spasm resisting full extension of the knees especially on the right side, though the knees were held in extension in walking. Abduction of both hips was quite free and there was no tendency whatever to adductor spasm in walking. There was practically no equinus and only slight varus on the left side, but on the right side there was a good deal of equinus, marked varus and marked internal rotation of the whole limb; all these deformities could be corrected by firm sustained pressure without setting up spasm. The pronator deformity of the right forearm was fixed and could not be corrected; on the left the forearm could be supinated almost to the full. The gait was enormously improved, but the internal rotation of the right leg caused the boy to walk with his feet wide apart. This result is most satisfactory but much further work remains to be done, which must take the form of peripheral operations.

The programme outlined for this patient on readmission to hospital is as follows:—

(1) Shifting the attachments of the gluteus medius and tensor fasciæ femoris lower down the ilium (Jones' operation), or section of the superior gluteal nerves on the right side.

(2) Lengthening of the tendons of the tibialis anterior and posterior on the right side.

(3) Detaching the insertion of the right pronator radii teres and transplanting it into the extensor carpi radialis longior.

Figure 1 is a photograph of this boy after the obturator nerves had been sectioned, but before the operations on the posterior tibial nerves.

Figure 2 is of a case recently admitted, showing the typical deformities of both upper and lower limbs. The photograph shows the attitude assumed during walking and is a good example

of cross-legged progression. This child, aged 12, is very intelligent and therefore a good subject for operation. A bilateral Stöffel on the anterior branches of the obturator nerves has been performed and the legs put up in plaster in abduction; at operation a certain amount of organic contracture was demonstrated and if this cannot be overcome by simple stretching the next stage will be a tenotomy of the adductor longus tendon on both sides, as it is essential that the adductor spasm be overcome before any attempt is made to tackle the deformities of the feet, the marked valgus in this case is secondary to the adduction and will tend to disappear when the normal line of weight-bearing is restored.

Two obturator neurectomies have also been done in infants with excellent immediate results in that the adductor spasm was completely corrected, but it is impossible to forecast the ultimate results and unless the after-care is intelligently carried out relapse is quite likely. The operation is difficult in infants on account of the small size of the nerves and the difficulty of identifying them in the abundant fat which lies between the muscles, but the advantage of early operation lies in the prevention of the development of permanent contracture, which is certain to occur in severe cases.

Osgood-Schlatter disease

Case II.—The patient, A. C., was an Anglo-Indian boy, aged 14½ years. His father died of pulmonary tuberculosis and a younger brother suffers from glandular tuberculosis. This boy has always been healthy except for infantile ailments. He is at school and takes part in all games and sports with great vigour. Six months ago he began to suffer from slight pain below the knee joints brought on by exercise and four months ago slight tender swellings appeared below the knee joints, which were painful after exercise and in the evenings, but better in the mornings after a night's rest. Rest always alleviated the pain and he never had any 'starting pains'. The condition is getting steadily worse.

On examination the tibial tuberosities were found to be slightly swollen and tender on pressure, but not reddened and there was no evidence of fluid in the swellings. The knee joints were perfectly normal, there was no limitation of movement, but there was pain over the tibial tuberosities on extreme flexion and on sharp extension. There was no limp in walking.

The radiogram (figure 3) shows the epiphysis of the tibial tubercle slightly separated from the underlying tibia, its lower edge broken off and the outlines slightly hazy. Both legs showed the same condition, which is a typical example of the disease described by Osgood in 1903 and by Schlatter a few months later. The tuberosity of the tibia arises from a tongue-like projection from the upper epiphysis with a separate centre of ossification. True partial separation of the tuberosity from trauma such as violent contraction of the quadriceps muscle occurs mostly in males of 16 to 18 and is unilateral. Osgood-Schlatter disease occurs at an earlier age, from 13 to 15, and though injury is to some extent an exciting factor, the symptoms come on insidiously and a clear history of injury or strain is unobtainable, as in the present case. Both knees are usually affected, the tubercle is enlarged and tender and pain is complained of after exercise, increased by full voluntary extension, since the epiphysis is pulled on by the contracted quadriceps muscle and

by passive complete flexion, as the epiphysis is then dragged upon by the stretched quadriceps.

The prognosis is excellent if the quadriceps muscle is thrown out of action for a time, allowing the epiphysis to settle down on the tibia again and the inflammation to subside. In the present case plaster-of-Paris knee caps were fitted to both knees for two months, after removal the knees were exercised daily for a month without weight-bearing and the patient was discharged free from symptoms. In some chronic cases it is desirable to limit knee flexion for about six months by fitting a knee cage with a stop allowing only 30° of flexion. No operation is ever necessary.

Osteo-chondritis of the hip: Legg-Perthes' disease

Case III.—E. B., Anglo-Indian boy, aged 12. Complained of difficulty in walking for six months and lately shortening of the right leg had been noticed. The onset was insidious, there was no definite history of trauma, merely a gradual development of a slight limp. There had never been any fever and there was nothing of importance to note in the previous history.

On inspection the right leg showed slight apparent shortening, amounting to ½ inch. The right great trochanter was more prominent than the left and there was a slight appearance of fullness in Scarpa's triangle. There was lumbar lordosis and when Thomas' test was applied by fully flexing the left hip joint it was found that the right hip joint was held flexed to 20°, it could be fully flexed, but extension was checked by muscle spasm. The right hip joint was adducted and only a slight degree of abduction was possible, the pelvis was raised on the right side to compensate the adduction, thus causing the apparent shortening. There was no real shortening and the trochanter was not raised above Nelaton's line. Rotation, especially internal rotation, was slightly limited. None of these movements caused pain unless an attempt was made to overcome the muscular spasm which was holding the joint in the abnormal position. The right thigh was slightly wasted. Walking was painless, but the patient limped on account of the flexed attitude of the joint and the limited movement. The left leg was quite normal. The radiogram (figure 4) showed the characteristic changes of the disease—a thin, sclerosed and fragmented epiphysis for the head of the right femur and thickening of the neck with bony absorption below the epiphyseal line.

This disease belongs to a class of affections of the epiphyses the ætiology of which has not yet been satisfactorily explained. In each country the disease is known by the name of the surgeon who first described it, so that different countries call them by different names, thus we have the names of Legg, Calvé and Perthes attached to this disease, though it was first described by Legg of Baltimore. Köhler's disease of the tarsal navicular, Köhler-Freiburg disease of the 2nd meta-tarsal, Keinboch and Preiser's osteoporosis of the carpal bones, epiphysitis of the vertebrae and of the calcaneus and several others are all probably of the same nature. The controversy turns on whether these conditions are of traumatic or inflammatory origin. Since these cases never terminate fatally and operation is not often indicated, there have been few opportunities for bacteriological and histological studies, the only points on which all writers

Fig. 3.

Fig. 2.

Fig. 4.

Fig. 5.

Fig. 7.

Fig. 6.

are agreed being that they are neither tuberculous, rachitic nor syphilitic. Legg considered trauma to be the sole determining ætiological factor, acting by interfering with the vascular supply of the epiphysis and leading to hyperæmia, which according to Leriche's view causes rarefaction of bone. In support of this theory is the frequency of a history of injury, the more common occurrence of the condition in boys, and its location in weight-bearing joints such as the hip or in epiphyses subjected to strain as in the tubercle of the tibia. At one time the infective theory appeared to be most convincing, as Legg himself grew cultures of *Staphylococcus aureus* from material scooped out from the femoral neck, and Phemister found definite histological evidence of an inflammatory lesion. These observations have not been confirmed, but the balance of evidence is in favour of the condition being due to the action of attenuated organisms circulating in the blood which settle in an epiphysis subjected to mild trauma. Hence the slight rise of temperature, swelling and pain which are often present in the early stages, the irritability of the joint as evidenced by muscular spasm and the fact that the disease is frequently bilateral. Our knowledge of its pathology is derived almost entirely from the study of radiological appearances. In the early stages the epiphysis becomes flattened and thinned out and may show division into several pieces—'fragmentation'. Later the fragments coalesce and recalcification is established. The head becomes flattened and as it expands 'creeps' out of the acetabulum. The upper part of the neck becomes expanded and shortened, and ill-defined areas of decalcification may form in its upper part, to be replaced later by areas of condensation. These changes may persist throughout life and definitely predispose towards osteo-arthritis at a later age. In 51 per cent a permanent limp and restriction of hip movements resulted. These cases are generally received with a diagnosis of early tuberculosis of the hip joint, but the diagnosis from tuberculosis presents no difficulty if one considers the freedom from pain, the good general health of the patient, and that only certain movements are limited. The radiogram settles the diagnosis at once.

This patient was anesthetized and the limb was put up in plaster of Paris in abduction, after correcting the adduction and flexion deformity. Three months later the splint was removed and a caliper walking splint was fitted. One month later the patient was discharged walking well and free from symptoms. The radiogram (figure 5) showed the head of the femur beginning to take on a shape approaching the normal, with less sclerosis.

As a rule one loses sight of hospital cases, but in this instance I am greatly indebted to Dr. Weldon, Chief Medical Officer, A. B. Railway, for sending me a report on the subsequent

progress of the boy and a radiogram (figure 6) taken in January 1933. It shows uniform density of the neck and epiphysis, some flattening and mushrooming of the head and flattening of the top of the neck with slight coxa vara, changes which are the reason for the name 'coxa plana' often given to the end-results of the disease. The caliper splint was worn for 18 months and then discarded as there was no pain or discomfort, movement in all directions was then almost normal and there was only a slight limp. Considering the marked deformities shown in the skiagram the clinical result is far better than one would expect. It is to be hoped that this result will be permanent, but it appears likely that the deformed articular surfaces will become the seat of an osteo-arthritis later, which will lead to permanent impairment of movement.

Case IV.—Arthritis of the hip joint producing changes similar to those of Perthes' disease.

N. B., Bengali Hindu boy, aged 12 years. No history of previous disease. Three months ago he slipped and fell on the right hip whilst playing. He was so severely injured that he was unable to rise and had to be carried home. Pain, fever and swelling of the parts around the hip joint followed and persisted for 8 to 10 days, after which the fever and swelling subsided, but the pain persisted and he has walked with a limp ever since. On examination the right side of the pelvis was found to be raised, the right thigh wasted and lumbar lordosis present. Thomas' test showed the right hip joint to be fixed in 20° of flexion and the limb adducted with gross limitation of abduction, so that only 15° of abduction was possible. The radiogram (figure 7) shows flattening, sclerosis and fragmentation of the femoral epiphysis. Areas of rarefaction are seen in the epiphysis, contiguous portions of the femoral neck and acetabulum. The radiologist reported that the appearances suggested pseudo-coxalgia with added infection.

The treatment was on the same lines as in case III, a plaster-of-Paris splint in abduction for two months and then a caliper splint to be worn for a year or more. On removal of the plaster splint the radiogram showed evidence of re-formation of the head of the femur, the sclerosis largely disappearing and some decalcification of the femoral neck, probably due to disuse. The patient was discharged after six months, walking in the splint without difficulty and with no apparent limitation of movement. He has not been seen since his discharge.

The interest of this case lies in the similarity of the x-ray appearances to those shown in figure 5. There is here a definite history of a traumatic arthritis following injury, with fever, pain, swelling and definite evidence of inflammation. In the previous case there was no such history, but the radiological appearances during the recovery stage are indistinguishable from those in case IV. The conclusion that the disease is of inflammatory origin seems clear from a comparison of these two cases, though the inflammation may be of such a low grade that in many cases it does not give rise to sufficient disability to attract attention. Cases such as this, of which several have come under the writer's notice, throw an interesting light on the ætiology of the disease.

The treatment of unreduced dislocation of the hip

In this country one frequently meets with cases of unreduced dorsal dislocations of the hip joint which have been out for more than three months, sometimes for a year or more. The advice given in the textbooks to reduce them by open operation is not always easy to follow. The operation, involving the complete stripping of all the muscles attached to the upper end of the femur, is a very formidable one and the scooping out of the filled-up acetabulum is no easy matter, even when this has been done it may be impossible to retain the bone in the acetabulum. If the operation is successful the joint is stabilized, but the range of movement is usually very small. In cases of over four months standing the operation is quite likely to fail and the head to slip out again. For such cases there is another procedure, which accomplishes the main object to be aimed at, the stabilization of the hip, without interfering with the joint and is therefore an operation attended with little risk; this is Lorenz's bifurcation sub-trochanteric osteotomy. The femur is divided just below the great trochanter by an oblique osteotomy and the lower fragment is forcibly abducted and pushed up to impinge against the pelvis below the acetabulum, which then takes the body weight. The result is to stabilize the hip and by permitting tilting downwards of the pelvis on the affected side to compensate the real shortening by an apparent lengthening, better called a 'functional' lengthening. The operation is not at all severe and after it is completed the limb is fixed in plaster for six months and then a caliper walking splint is fitted. The upper fragment unites with the side of the lower fragment and the result is a strong union with a slight degree of movement between the lower fragment and the pelvis, giving excellent function compared with the condition of the patient before operation.

Ankylosed hip joints with adduction deformity

Cases in which the hip joint has been allowed to ankylose in extreme adduction—usually a firm fibrous ankylosis—are extremely common, following gonorrhœal or rheumatoid arthritis. It is usually impossible to break down the adhesions in the joint, as there is much decalcification and atrophy of bone, so that fracture of the neck of the femur with the risk of non-union is very likely to occur if the attempt is made. In these cases there may or may not be real shortening, but there is functional shortening due to the adduction, which raises the pelvis on the affected side by as much as two inches. Lorenz's bifurcation osteotomy is by far the best operation for these cases, achieving a better result than the old simple sub-trochanteric osteotomy. By abducting the femur the pelvis will come to be tilted down on the

diseased side when the legs are parallel and thus functional lengthening will be made to counteract real shortening; as much as 2 inches may thus be gained. The axis of the femur comes to lie under the line of weight of the body instead of outside it and there is a wide area of contact between the pelvis and the upper end of the femur, by which the body weight is transmitted. The writer has performed this operation several times with most satisfactory results and has come to prefer it in such cases to the tedious method of gradual forcible breaking down of adhesions with fixation in plaster, involving several anæsthetics and much painful after-treatment. Figures 8 and 9 illustrate well the principles of the operation.

My thanks are due to Dr. S. G. Galstaun, Hon. Radiologist to the Medical College Hospital, for the radiograms which illustrate this paper.

CREEPING ERUPTION PRODUCED BY HOOKWORM LARVÆ

By P. A. MAPLESTONE, D.S.O., M.B., CH.B., D.T.M.
(From the Hookworm Research Laboratory, School of
Tropical Medicine, Calcutta)

DALGETTY (1901) defined and described 'water-itch' in tea-garden coolies. Bentley (1902) wrote a valuable paper on the subject which it is proposed to abstract on account of its historical interest and because it appears to have been overlooked by most workers during recent years.

The condition of 'water-itch' or 'pani-ghao' is well recognized in tea gardens in Assam, Cachar, and Sylhet, and a similar affection has been noticed in sugar plantations in the West Indies, according to the report of the surgeon-general for Trinidad for 1900. The condition is always associated with the presence of the larvæ of *Ancylostoma duodenale* in the soil. There is a definite seasonal incidence, the disease being common in wet weather and absent in the dry season; all classes of the community may be attacked, but it is not common in Europeans. It attacks individuals with a frequency directly proportional to their exposure to infection and everything points to the earth being its source.

The first symptom is itching and burning, and within one to twenty-four hours a slight papular eruption occurs though at times only a slight erythema is visible. If treated early this eruption may be aborted in two or three days, but if allowed to run its course vesicles which form are liable to burst and to give rise to ulcers, or they may become pustular and unless speedily opened the secondary infection may spread and burrow under the surrounding skin so that extensive ulceration and sloughing may take place.

Scheult and Trinidad considers the disease is caused by a chemical irritant in the soil, and Dalgetty considers it allied to scabies and caused by a similar parasite. The following experiments were made to test the above theories:—(1) A small amount of soil known to be infected was collected and divided into two parts and one part was applied to the arm for about six hours where it produced a typical water-itch. Both the soil from the arm and the unused portion were then examined and no mites were found in either sample, but among other organisms present hookworm larvæ were identified in the unused sample, but they were not found in the portion that had been on the arm. (2) A portion of the same earth was 'sterilized by being baked', and when moistened and placed on the arm no reaction was seen, thus disposing of the chemical irritant theory.

Numerous cases of water-sore were investigated; blood films taken from infected areas, when only in the erythema stage, showed nothing abnormal, but in surface scrapings from similar spots on the skin, discarded sheaths of hookworm larvæ were recognized.

To prove the source of infection, soil was sterilized by heat and after moistening it was inoculated with faeces containing hookworm eggs, and a control culture was made with faeces in which hookworm eggs were not found. After incubation at air temperature for a week the first culture was found to contain many hookworm larvæ and in the second one none were found. These cultures were each divided into two parts, and one part of each was dried, the others being left moist. All four samples were now applied to arms of volunteers and left for about eight hours. The site of application of the untreated portion of the positive culture exhibited typical water-sore lesions, the other three sites only showed slight transient erythema. Examination of the four soil samples after removal from the skin showed in the first untreated portion only a few dead larvæ, in the treated portion of this culture were many dead larvæ, and the other two from the negative culture were still negative. Examination

of both the dried and undried cultures that had not been placed on the skin showed that the drying had killed the larvæ. The results of these experiments are in accord with the epidemiological fact that water-sore is common in the wet season and absent in the dry weather.

In the light of later information it is probable that Bentley's observations apply to *Necator americanus* as well as to *A. duodenale*, but the former species had not been identified when he wrote his paper, so all his references are to the latter worm.

From Bentley's description of the vesicular stage of the eruption it is clear that he saw the type of lesions now known as creeping eruption, but probably owing to the fact that his cases all had multiple infections the intertwining of the individual tracks masked their linear nature.

In the description by Looss (1911) of infections on his own skin with hookworm and strongyloides larvæ, he says that he produced lesions of a linear character similar to those proved by Russian workers to be due to fly larvæ. He first noted this in 1898, so this is apparently the first record of the association of creeping eruption with hookworm larvæ which the following quotation makes clear. 'Personally I have not the least doubt that in my case only a migrating *Agchylostoma* or *Strongyloides* larva can have been the cause of the phenomenon; in the attacks before 1904 only *Agchylostoma* larvæ'.

But the first association of creeping eruption with a nematode is that of Levinsen (1889), who identified a worm taken from a Siamese woman as *Cheiracanthus siamense*, which was later renamed *Gnathostoma siamense* by Leiper (1909). These records of Looss and Levinsen should be clearly distinguished from that of Lee (1874) who first used the name creeping eruption without finding the cause; it was probably a fly larvæ in his case, however, because it occurred in England. A great many of the earlier records of creeping eruption give no cause at all or assume it was due to fly larvæ. Many of these references are American, and on account of the uncertainty of the etiological factor it is not considered worth while discussing these papers in detail, therefore the reader is referred to a paper by Klauder and Greenbaum (1921) who give a long list of references. Many of these papers are of interest because those cases which are reported from the Southern States, or mention a definite association between contact with sand and the appearance of the eruption, are almost certainly due to hookworm larvæ. Although the records of hookworm creeping eruption probably begin with the publication of a paper by van Harlingen (1902) the first really important contribution to the subject was a paper by Kirby-Smith (1915) in which he describes thirty cases seen by him in Florida; he differentiates it from uncinariar dermatitis or 'ground itch' which is

common in this area. Even now that the etiological factor is clearly proved certain workers maintain this distinction.

Parham (1916) reported one case and recorded seeing another in South Carolina both of which were probably hookworm infections in view of the region in which they occurred. Fülleborn and da Rocha-Lima (1919) discuss creeping eruption with special reference to West Africa; they lay greatest stress on *Gastrophilus* larvæ as the causative parasites, but they refer to Looss' record of its production by *ancylostoma* and *strongyloides* larvæ. There is an account of a single case by Ketron (1921) which is of interest because although the cause is not given it is apparently the first record of a cure by the use of a freezing agent.

Kirby-Smith (1925) gave another useful contribution describing the clinical and epidemiological manifestation of this disease, in Florida particularly; in this paper he records his experience of fourteen years in which he saw 2,500 cases. Although the actual cause was still undiscovered a special analysis of 300 of these cases showed that 95 per cent of them had a history of contact with damp sand. In a further study of the disease Kirby-Smith, Dove and White (1926) report the finding of nematode larvæ in five out of forty-eight portions of excised skin. The larva was reconstructed from serial sections and given the name *Agamone-matodum migrans*, and Dr. B. H. Ransom to whom the material was referred stated that it was a third stage larva of a species in the superfamily *Strongyloides*. The context shows that this is obviously a misprint for *Strongyloidea*. It is also of interest that in this paper they trace some connection between soil contaminated with human faeces and creeping eruption. Shinn (1927) reported a single case in which the parasite was not found but in which there was a history of contact with damp sand. Cultures of the faeces of dogs and cats infected with *A. braziliense* and *A. caninum* were made by White and Dove (1927) and applied to their own skins; they produced typical lesions of creeping eruption.

Hamilton (1927) in Australia recorded a case of a child, accustomed to go barefoot, with creeping eruption on both feet. No parasite was found; but in the light of the work of Heydon (1929) this was probably a case of hookworm creeping eruption. From a series of experiments White and Dove (1928) came to the conclusion that the larvæ of *A. braziliense* caused creeping eruption, but those of *A. caninum* failed to do so. Shelmire (1928) records the results of the infection of eighteen individuals each with about one hundred larvæ of *A. braziliense*; sixteen developed typical lesions, and there was no evidence of intestinal infection afterwards. He also states that creeping eruption and ground itch are quite different. Cawston (1928) reported a similar skin disease in South Africa locally known as 'sand-worm

disease' which is probably hookworm creeping eruption. Eight cases of creeping eruption from Lagos, West Africa, were described by Smith and Elmes (1928), but the causal parasite was not mentioned. A useful clinical account is given by Smith, Dove and White (1929) but it adds no new facts. Heydon (1929) records creeping eruption as common in Townsville, Australia, where both cats and dogs are heavily infected with *A. braziliense* and *A. caninum*. He produced artificial creeping eruption with the larvæ of both species, but failed to find evidence of intestinal infection in any of his cases. He also notes that the length of the tracks varies in different experiments on the same individuals. Larvæ of *Uncinaria stenocephala* were used by Fülleborn (1927) to produce creeping eruption in man. In a further communication on experimentally-produced creeping eruption, White and Dove (1929) reach the conclusion that *A. caninum* larvæ typically produce papules without linear lesions, and that *A. braziliense* larvæ produce the linear eruption, but to what extent the latter produce papules and to what extent the former produce lines as well as papules is not established. A long paper by Hume (1930) is only an account of the condition with no new facts and it contains a long list of references most of which are not cited in the text. Le Sueur and Hutchison (1930) give an account of two cases from Sarawak, Borneo, one of which they state was caused by *A. caninum*, but the evidence for this is somewhat inadequate. Apart from this, however, this report is of value because it is a record of severe natural infections in the eastern hemisphere, and also because it gives an account of the successful treatment of a long-standing case with oil of chenopodium. Another long paper by Dove (1932) is mainly a résumé of the work of himself and his co-workers, Smith and White, but a considerable amount of fresh experimental work is included which will be discussed below in relation to the writer's findings.

Present investigation

In all the experiments recorded below the larvæ were grown on earth previously heated to kill all natural nematode infections. The eggs used in these cultures were obtained from dissected worms which were identified before dissection, or in the case of animals intestinal contents were sometimes used, but only after it had been ascertained post mortem that only one species of hookworm was present in the gut. The larvæ were allowed to grow at room temperature for nine to twelve days, then extracted by Baermann's method overnight, and placed on the skin next morning. The method of inoculation was to place the stated number of larvæ on the skin in water by means of a pipette, and then to sprinkle on sufficient finely-divided helminthologically-sterile soil to take up the

water and prevent it running off. This was covered with a bandage and left for about an hour, when the soil was washed off.

In each group of experiments larvæ from a single culture were employed.

Group I. Twenty larvæ of a nine-day-old culture were placed on the flexor surface of the forearm of each individual.

Nos. 1 and 2. Hindu—Bengali—hospital patients suffering from asthma. No intestinal helminths present. No reaction. No eggs in stools up to thirty days after inoculation.

No. 3. Hindu—Bengali—medical man engaged on laboratory work. No intestinal helminths present. No reaction. No eggs in stool up to sixty days after inoculation.

No. 4. European—medical man engaged on laboratory work. No reaction. Stool not examined.

No. 5. Punjabi—medical man engaged on laboratory work. No intestinal helminths present. Stool negative one month after inoculation.

25th May, 1932. Itching felt three to four hours after inoculation. Nothing visible.

26th May, 1932. Three small papules present.

27th May, 1932. Four papules. Slight itching.

28th May, 1932. Papules unchanged. Two lines about two centimetres in length leading from two of the papules.

29th May, 1932. No change.

30th May, 1932. Lines gone and a fresh papule about three centimetres above the original group.

4th June, 1932. All signs gone except slight redness.

No. 6. European—medical man engaged on laboratory work. Slight mixed infection with *A. duodenale* and *N. americanus*.

25th May, 1932. Slight itching in less than half an hour after application of larvæ. On removal of bandage in one hour a small papule surrounded by an area of erythema about two centimetres in diameter was noted. Three hours later the redness had gone and a second papule was present.

26th May, 1932. Vesicles on summit of papules. Slight itching.

27th May, 1932. Vesicles coalesced and growing bigger, surrounded by erythema. Area of œdema about seven centimetres in diameter surrounded by erythema with vesicle in centre. Itching slight and intermittent. No pain or tenderness.

28th May, 1932. Vesicles somewhat enlarged with a palpable line about two centimetres long leading from the central lesions. Œdema unchanged.

29th May, 1932. Vesicles unchanged. Line gone. Œdema lessened. Itching stopped.

30th May, 1932. Vesicles unchanged. Œdema gone. Vesicles opened and dressed with dry boracic acid powder.

The lesion gradually healed and disappeared without further signs or symptoms.

Group II. Thirty larvæ from an eleven-day-old culture of *A. braziliense* from a cat were placed on the flexor surface of the forearm of each individual.

The first six cases in this group were all hospital patients and natives of Bengal.

No. 7. Hindu, male, aged 8 years. Disease, kala-azar. Ascaris and trichuris infection present.

15th June, 1932. Itching within three hours of inoculation. No signs.

16th June, 1932. One small papule. No itching.

17th June, 1932. Two papules very close together. Slight œdema. Burning sensation.

18th June, 1932. Vesicles formed over papules and coalesced. Œdema less.

27th June, 1932. Gradual subsidence from third day. All signs gone. No hookworm eggs in stool up to six weeks after inoculation.

No. 8. Hindu, male, aged 25 years. Disease, kala-azar. Hookworm eggs in stool before inoculation.

15th June, 1932. Itching within three hours of inoculation. No signs.

16th June, 1932. One papule. Slight itching.

17th June, 1932. Three papules. Itching with signs of scratching. Gradual subsidence with nothing further of note except recurrence of itching without any signs, one week after inoculation. Stool not examined.

No. 9. Indian Christian, male, aged 50 years. Occupation, laboratory attendant. Stool negative prior to inoculation. No reaction until twelve days later when a patch of œdema about five centimetres in diameter appeared at the site of inoculation. There was slight tenderness and the man said he could feel something moving. No further signs developed and all were gone one week after their onset. The stool was negative up to thirty-seven days after inoculation.

No. 10. Hindu, male, aged 20 years. Occupation, nil. Disease, hookworm infection. Itching on day of inoculation, with no signs. Nothing more noted. Stool not examined.

No. 11. Hindu, male, aged 10 years. Disease, ascariis infection.

15th June, 1932. No reaction.

16th June, 1932. One papule. Occasional itching.

17th June, 1932. Vesicle formed over papule—surrounding small area of erythema. Itching.

18th June, 1932. Two fresh vesicles near original one. Itching increased. No fresh signs or symptoms, and all lesions gone within eight days of inoculation. Stool not examined.

No. 12. Hindu, male, aged 38 years, clerk. Disease, kala-azar. No helminth ova in stools.

15th June, 1932. No reaction.

16th June, 1932. Several deep papules, can be felt but not seen—itching.

17th June, 1932. Small papules visible.

21st June, 1932. All signs gone. The stool was negative until thirty-six days after inoculation when three or four hookworm eggs were found by Lane's centrifuge. These eggs were unusually small measuring only 0.053 mm. in length. The patient was treated the following morning with carbon tetrachloride and oil of chenopodium, and on the following day a single female *Ancylostoma braziliense* was recovered.

No. 13. European. The same individual as no. 4, group I. No reaction. The same person was submitted to a third inoculation with twelve larvæ from a twelve-day-old culture without any result. Stool never examined.

No. 14. Punjabi. The same individual as no. 5, group I. Stool negative.

15th June, 1932. Inoculated on both forearms. The inoculation on the left side was at the same spot as the first inoculation. Three hours after inoculation there was no reaction on the left arm, but slight itching on the right arm.

16th June, 1932. Left arm—one papule. Right arm—two papules.

17th June, 1932. Left arm—two papules. Right arm—no change.

18th June, 1932. Left arm—vesicles. Right arm—vesicles.

Vesicles dried up and all signs gone by 23rd June, 1932.

18th July, 1932. Hookworm eggs in stool by Lane's centrifuge. Eggs small, similar to those in no. 12.

24th July, 1932. Treated with CC14 and oil of chenopodium. No worms recovered.

No. 15. Hindu, medical man. Occupation, laboratory worker. Stool negative before inoculation.

15th June, 1932. Slight itching within three hours of inoculation. No signs.

16th June, 1932. Five discrete papules close together.

17th June, 1932. Six papules—all slightly larger—no itching.

18th June, 1932. Vesicle formation with tendency to coalesce.

20th June, 1932. One fresh papule about five centimetres to right of original group—itching again felt.

21st June, 1932. All but last-formed papule disappearing.

25th June, 1932. All papules again swollen and itching with a fresh one to the left of the original group.

27th June, 1932. Slight increase in size—itching still troublesome.

30th June, 1932. All signs nearly gone.

18th July, 1932. A few small hookworm eggs in stool.

22nd July, 1932. Treated with CC14 and *ol. chenopodium* and two female *Ancylostoma braziliense* obtained from the stool on the same day.

No. 16. Hindu, medical man. Occupation, laboratory worker. Stool negative.

15th June, 1932. Slight itching within three hours of inoculation. No signs.

16th June, 1932. No signs or symptoms.

17th June, 1932. Two reddish macules—no itching.

18th June, 1932. Macules gone—one small papule appeared.

20th June, 1932. Papule increased and two fresh ones present—itching marked.

21st June, 1932. No change—itching less.

24th June, 1932. Subsiding.

21st July, 1932. A few small hookworm ova in stool. In this case immediate treatment was not possible and when the stool was examined on 1st August, 1932, it was negative, and remained so on three or four subsequent examinations. This was apparently a transient infection.

No. 17. Mahomedan. Occupation, laboratory attendant. Hookworm and ascaris infection.

15th June, 1932. Slight itching within three hours of inoculation. No signs.

16th June, 1932. A single large papule with vesiculation.

17th June, 1932. Began to subside and no signs one week after inoculation.

21st July, 1932. Treated with CC14 and *ol. chenopodium* and two female *Necator americanus* recovered.

22nd July, 1932. Four male and two female *N. americanus* and one male ascaris recovered.

Not included in group II.

No. 18. European, medical man, the same individual as no. 6, group I.

27th June, 1932. Inoculated with ten larvæ of *A. braziliense* from a different culture, on the flexor surface of the left forearm. No reaction. Two other larvæ from the same culture were placed on the flexor surface of the left wrist and itching was felt about four hours afterwards with the formation of a small wheal.

28th June, 1932. Wheal replaced by a large red macule, in the centre of which a group of small vesicles are visible with a hand lens.

29th June, 1932. Track formation beginning with intermittent itching. This continued at intervals until 2nd July, 1932, from which time the lesion began to subside without treatment. The total length of the track was not more than six centimetres.

Group III. Thinking the comparative lack of reaction in all the above cases might be due to unusual thickness of the skin a series of four Indian hospital patients were taken and were all inoculated on three different parts of the body where the thickness of the skin is of marked difference. The spots where each one of the four persons was inoculated were the extensor and flexor surfaces of the forearm, and the web between the great toe and the second toe of the foot. Fifteen larvæ were placed on each spot and there was no reaction in any of the cases. These experiments were carried out in November, and although it was somewhat cooler than when the earlier experiments were done the difference in temperature was not considered sufficient to have any effect on the result.

Ancylostoma caninum.—Eleven individuals were utilized in experiments with larvæ from this species of hookworm, and twenty-six inoculations were performed altogether. The method of preparing larval cultures and of inoculating them was exactly the same as in the case of *A. braziliense*, so it needs no detailed

description. About thirty larvæ were placed on the skin on each occasion. Most of the results were entirely negative, but in a few of them small papules or tracks, never more than three centimetres in length, were noted; in the cases showing these signs there was a slight amount of itching. All signs of larval activity in the skin disappeared in a few days in all instances, and in none of the cases in which stool examinations were frequently made was any evidence of intestinal infection found. The people used in this series were with one exception, who was an Anglo-Indian, all Indian inhabitants of Bengal similar to those mentioned in the *A. braziliense* groups.

One other person, the same European as no. 6, group I, was twice inoculated with *A. caninum* larvæ.

On the first occasion four larvæ were placed on the radial side of the left forearm a little above the wrist, and for two days there was no reaction, when a moderately hard deep wheal developed accompanied by some itching. Nothing further was noted and the lesion gradually disappeared. A second inoculation with a single larva was made two inches above the first but three days later. A vesicle surrounded by erythema and slight deep swelling appeared the following day. The condition appeared to be subsiding but three days after the inoculation a large wheal near the original vesicle suddenly appeared and was intensely itchy, by the next morning the wheal had gone and in its place there was a track curved on itself, and of a total length of about four centimetres. No further signs or symptoms occurred and the lesions gradually disappeared.

Ancylostoma duodenale.—Six tea-garden coolies in hospital with Naga sore (tropical ulcer) were utilized in this experiment. Four were Nepalis, and two were Hindus, and all of them had hookworm infection. The larvæ were obtained from cultures of worms removed from human beings post mortem. The site of inoculation was the flexor surface of the right forearm, and only ten larvæ were used on each, because of the pathogenicity of this species.

Eruption on forearm of a Nepalese coolie on the fourth day after inoculation with ten *Necator americanus* larvæ.

Three of the cases had no reaction and the others had papules going on to vesicle formation with short typical tracks leading from them; all signs had vanished within six days of inoculation.

Four more hospital patients were inoculated on another occasion on both the flexor and extensor surfaces of the forearm and only one of them showed any reaction and this was similar to the positive results in the first series. It is interesting to note that the reaction appeared on both front and back of the forearm so

that the thick skin of the back was no more resistant than the thinner skin on the front.

Necator americanus.—The six patients in the first series of *A. duodenale* experiments were inoculated at the same time, on the flexor surface of the left forearm each with ten larvæ of *N. americanus* procured in the same way as those of *A. duodenale*, and they all showed a definite vesiculo-papular eruption of linear type at the site of inoculation. The most extensive lesion was that shown in the illustration, and even this one had practically disappeared in ten days without treatment. Nine other persons, eight Indians and the European, no. 6, group I, were inoculated on different occasions and all gave a positive reaction with definite lines of vesicles, but none were so marked as in the case illustrated above. It is of interest to note that three of these inoculations were done in January of this year while the weather was exceptionally cold, so that a high temperature does not appear to have much influence in producing positive results.

The six coolies treated with *A. duodenale* and *N. americanus* larvæ gave three positive results with the former and six with the latter species, so it was thought that they might be particularly susceptible to this type of infection. They were accordingly all given an inoculation on the forearm with twenty larvæ of *A. caninum* with entirely negative results.

Discussion

It was pointed out by Maplestone (1929) that creeping eruption as seen in the United States of America and elsewhere is apparently absent from India, and the same thing has been noted by Africa (1932) in the Philippine Islands. Africa, however, produced severe creeping eruption in two Filipinos with larvæ of *A. braziliense* grown in the Philippines. He suggests as an explanation of the absence of this condition in nature in these islands that there may be a different race of *A. braziliense* in the East Indies and in America, and that the eastern strain having been fairly often recorded as a human parasite is better adapted to the human host than the American strain which has only once been found in man by Gordon (1922). The result is that the eastern strain passes directly through the skin to the gut, while the American strain not being adapted to the human gut wanders in the skin. His own experiments with the eastern strain appear to upset this theory, which is further discounted by Dove (1932) who mentions making use of a boy in his experiments who was found in Texas naturally infected with *A. braziliense*, and who from the description of the use made of his stools carried this infection for a fairly long period. Another objection to the race theory is that in Australia and probably in Borneo, both countries in the same zoological area as the Philippine Islands, strains of hookworm larvæ exist that are capable of producing severe creeping eruption. In his work Dove (1932) made cross-breeding experiments with strains of *A. braziliense* from different parts of the Southern United States. The adults of these strains showed slight morphological differences, and he showed there was no specific difference, therefore, if different strains of this species do exist, morphology is not likely to be of any more use in differentiating them than

it is in the case of the ascaris of man and the pig. Dove also found that larvæ cultured direct from the stool of the boy with *A. braziliense* infection only produced an abortive eruption whereas after passage through a cat the larvæ from this strain of human origin produced a typical eruption which persisted for at least thirty days. This does not agree with my findings, for all the larvæ of *A. braziliense* used by me, all of which failed to produce more than an abortive eruption when they produced any at all, were cultured direct from worms which came from cats.

At a later stage in his experiments, using material from the same boy, Dove infected previously-worm-free human beings, cats and dogs with larvæ grown from his stools, and, in the subsequent examination of the infected persons and animals, recovered *N. americanus* and *A. caninum*. He assumed that the boy's infection had changed from one of simple *A. braziliense* to a mixed one with *N. americanus* and *A. caninum*. He offers no explanation how this strange alteration of species might have occurred, and in the writer's opinion this statement must be accepted with reserve, especially in the case of *A. caninum*, for as far as can be ascertained there is only one record of this species being found in human beings and that is by Manalang (1925).

Whatever the factors may be, and for these none of the existing theories offer an explanation, it seems clear from the above experiments that severe creeping eruption, if it exists in India at all, must be very rare. As far as my experience goes with different races of host in these experiments, there is no evidence that race has any influence on the amount of skin reaction to hookworm larvæ of any of the four species employed. There is a slight indication of individual sensitiveness however, for no. 6, group I, was carrying a light mixed infection at the time of inoculation, and what is probably more important, has been engaged on helminthological work for many years. The type of reaction produced in this instance had certain allergic signs and it is of interest to note that the description of what was probably *N. americanus* infection in an endemic area given by Smith (1904) could be fairly well applied to the first lesion in this case. That special sensitization to nematode proteins may be produced in man is shown by Fülleborn (1930) who described a very severe reaction involving his whole arm and arising after infection with probably only one *A. caninum* larva. He has sensitized himself by repeated experimental inoculations over many years.

It is held that the larvæ of *A. braziliense* always, and of *A. caninum* occasionally, produce creeping eruption because they are wandering in the skin of an unsuitable host. This theory presupposes an undue amount of prophetic knowledge or instinct in the larvæ, for it is difficult to believe that the larvæ remain in the

skin because they are aware the intestine of the animal in which they happen to be is unsuitable for them in their adult stage. The present series of experiments indicate that this theory is not tenable, for as far as creeping eruption can be produced in India the larvæ of *N. americanus* appear to be the most certain and most active species in causing a skin eruption.

In all the experiments of other workers, quoted above, intestinal infection with *A. braziliense* has never been found in man. After my own experience this is not surprising for by using Lane's centrifuge only three or four eggs were found on a slide and as far as can be judged the infection only lasted a very few days, therefore I am convinced I would have missed the infections I discovered, had I used any other method of stool examination.

With regard to the name 'creeping eruption' it is stated by certain Americans who have written on the subject that this condition and ground itch are quite distinct. Although I have never seen a case of severe creeping eruption I feel convinced, from comparison of my mildest and most severe cases, that the lesion is essentially the same and that the difference is only in degree. Further, the more persistent and extensive a creeping eruption is the more liable it is to secondary infection, which has nothing to do with the primary lesion. These attempts to differentiate different types of creeping eruption will in the end only confuse and complicate the matter in the way that so many of the older skin diseases are already confused.

It has also been suggested that 'creeping eruption' should be specially reserved for this disease in the Southern United States, because it was there that the cause was first proved. Although this argument has some claim to consideration when Lee's original use of the term is considered, it is of no value against Levinsen's case because a gnathostome larva was identified as the cause in this instance in the year 1889. Therefore, if the title to creeping eruption as a name is to depend on the finding of the cause, gnathostome creeping eruption must have it. It may have been noticed that in the present paper the phrase 'hookworm creeping eruption' has been used once or twice. This is not with any idea of creating a name but it was found short and explanatory for the subject under discussion in the context.

Almost all the papers that have hitherto appeared on creeping eruption have given a long history of the condition and have included references to it, whatever has been the cause. This must all be so well known to workers on the subject by now that it has not been repeated here, but an attempt has been made to separate the history of hookworm creeping eruption from the other varieties, and so clarify the subject.

THE ARNETH COUNT, WITH PARTICULAR REFERENCE TO ITS DIAGNOSTIC VALUE IN ASTHMA

By HUGH W. ACTON, C.I.E.
LIEUTENANT-COLONEL, I.M.S.

Professor of Pathology and Bacteriology and Director
and

DHARMENDRA, M.B., B.S.

Assistant Research Worker,
Calcutta School of Tropical Medicine

The Arneth count.—The neutrophilic polymorphonuclear cell develops from a mononuclear cell with a single round nucleus. The myelocyte passes through an intermediate stage with a single indented nucleus (metamyelocyte), but with no true nuclear lobulation. It is evident, therefore, that the cell with a simple round nucleus is younger than that with an indented nucleus and this form is younger than the true polymorphonuclear cell. Arneth (1904) argued from this line of thought by contending that a polymorphonuclear cell with only one lobe was younger than one with two lobes and so on. He studied blood smears from many different cases of acute and chronic infections and stated that very important morphological changes were found in the nuclei of polymorphonuclear neutrophilic leucocytes. He divided these cells into five classes, the division being based on the shape of the nuclear material:—

Class I containing cells with one round or indented nucleus.

Class II containing cells with two nuclear divisions.

Class III containing cells with three nuclear divisions.

Class IV containing cells with four nuclear divisions.

Class V containing cells with five or more nuclear divisions.

Each class has subdivisions according to the shape of the nuclear portion, whether round or s-shaped, making twenty-five types in all. Arneth counted one hundred polymorphonuclear cells and arranged them in his five classes like this:

I	II	III	IV	V
5	35	41	17	2

This expression is known as the Arneth count.

Arneth stated that the percentage of cells in the various classes varied only within normal

limits in health, but changed in infectious conditions, the change usually being in the direction of an increase in the percentage of classes I and II and a decrease in classes III, IV and V; this he spoke of technically as a 'shift to the left'. Particular emphasis was laid on the prognostic value of this classification in pulmonary tuberculosis. Arneth's classification did not define when a nucleus might be considered as divided and so allowed the personal factor to assert itself unduly. To rectify this Cooke (1914) has given a criterion of nuclear lobulation—'If there is any band of nuclear tissue except a chromatin filament connecting the different parts of a nucleus, the nucleus cannot for the purpose of the Arneth count be said to be divided'; when the count is made according to Cooke's method the average normal figures vary considerably from those obtained with Arneth's method. Cooke (1914 and 1928) gives the following figures as the average normal:

I	II	III	IV	V
10	25	47	16	2

Schilling (1920) simplified Arneth's classification by dividing the neutrophilic cells into the following four groups.

Group I myelocytes.

Group II young metamyelocytes (with only the slightest indentation) of the nucleus.

Group III older metamyelocytes (with deep indentation but no true lobulation of the nucleus).

Group IV polymorphonuclears.

In doing the ordinary differential count of leucocytes, each of these types is counted separately, so that in the result each variety of neutrophilic granular cells is expressed as a percentage of the total number of leucocytes; in Arneth's method they are expressed only as a percentage of the total neutrophilic cells. As a normal figure Schilling gives neutrophilic granular cells 67 per cent—these are composed of 63 per cent polymorphonuclear and 4 per cent of old metamyelocytes (band forms). The young metamyelocytes and myelocytes are absent from the normal blood.

Pons and Krumbhaar (1924) have proposed a further simplification in the Arneth count. They believe that essential clinical purpose is served if all neutrophils are subdivided into three groups as under

- (1) Metamyelocytes (very young) with round or slightly indented nuclei.
- (2) Non-segmented forms (young) where the nuclear material is connected with broad bands.
- (3) Segmented forms (older) where two or more groups of nuclear material are connected by narrow strands of filaments.

Roberts (1927) has recently proposed a still further simplification of the Arneth's classification in which the polymorphonuclear neutrophils are divided into only two groups 'lobulated' and 'non-lobulated'. Roberts states the number of non-lobular forms to be 25 per cent. A non-lobular count of 35 per cent or over (except during menstruation when a normal count may rise up to 35 per cent) is indicative of an acute inflammatory process.

The Arneth index.—In Arneth's count the result is expressed in five sets of figures which is rather cumbersome and it was desirable to replace such an expression by a single figure. Many ways of doing this have been suggested.

(1) Arneth took the sum of the cells in the first two groups as the index.

(2) Bushnell and Treuholtz (1908) proposed the sum of the cells in group I and group II and one half of

the cells of group III. This index is commonly used as the Arneth index.

(3) Ponder and Flinn (1926) suggested the following:

The cells of each group are multiplied by the number of the group (group I by 1, group II by 2, and so on), the results added, and the total divided by the number of cells counted. The average normal index thus computed is 2.7.

(4) Hamilton-Black's (1913) index is obtained by multiplying the number of cells in class I by 10, the number of cells in class II by 18, the number in class III by 22, and the number in class IV by 25, 100 cells being dealt with altogether. Normally it is about 2,000 and cannot be less than 1,000. It is based on a finding that the phagocytic activity of the cells of various classes are as 10 : 18 : 22 : 25. The use of this index implies the acceptance of these figures for phagocytic ratios, but Ponder and Flinn (1926) were unable to find any significant difference between the phagocytic activity of the various Arneth classes of the polymorphonuclear cells. Ponder (1928) concluded that, so far as diapedesis and phagocytosis *in vitro* were concerned, the cells of various Arneth classes were indistinguishable, for the increase in the nuclear lobulation which occurred with the increasing age of the cell did not apparently enable the cell to pass more readily from the vessels and lymph spaces into infective cavities, nor did it render more active as a phagocyte.

The experimental confirmation of Arneth's theory regarding the age of the polymorphonuclear leucocyte and conformation of the nucleus.—Colbert (1924) using vital stains confirmed Arneth's view of the significant relation between the shape of the nucleus and the age of the cell. In the films he identified several neutrophils with unsegmented nuclei and repeatedly traced the outline of an individual nucleus for three hours. In no instance did any nucleus, once identified as an unsegmented type, become segmented under observation. He is of the opinion that the constant shape of the neutrophile nucleus in the living state for several hours supports the view that the shape of the nucleus was not an accident but bore a definite relation to life history of the cells.

The study of the effect on the Arneth count of substances which stimulate the bone marrow to rapid and increased production of leucocytes provides evidence in favour of Arneth's assumption that the cell with a one-lobed nucleus is younger than that with two, and so on. Lim, Sarkar and Brown (1922) had shown that thyroid substance definitely stimulated the bone marrow in rabbits and this substance has been used by Ponder and Charipper to study the effect on the Arneth count when bone marrow was stimulated. Ponder (1924 and 1926) found that in rabbits repeated injections of thyroid resulted in markedly increasing the percentage number of polymorphonuclears with a simple (immature) nucleus which he thought was due to thyroid stimulating the bone marrow, resulting in the increased production of an immature type of cell. A single injection of thyroid produced a deflection of the Arneth count, a large number of cells of class I being introduced into the circulation; subsequent changes in the count were followed and it was shown that the cells of class I developed in the blood stream into cells of class II, these into cells of class III and so on until class V was reached. Charipper (1929) showed the same effect of thyroid on the Arneth count of a perennibranchiate amphibian.

Another substance definitely known to effect the bone marrow is benzol. Weiskotten and others (1915, 1919 and 1924) have shown that subcutaneous injections in rabbits of an olive-oil and benzol mixture first caused a rapid decrease of leucocytes in the peripheral circulation after which a primary rise occurs, this is followed by a secondary fall and a secondary rise. They noted that the phenomenon was accompanied by a marked aplasia of the bone marrow following the injection with active regeneration occurring at the time of secondary rise. Hunt and Weiskotten (1930) thought that

experimental verification of the interpretation of Arneth's classification would be possible in the conditions brought about by benzol injection. A marked leucopenia was followed by a large number of polymorphonuclear leucocytes being produced rapidly and passed into circulating blood, so that leucocytes known to be in varying stages of life cycles could be studied. From his study he concluded that cells with single-lobed nuclei were young or immature forms, and that the number of lobes increased with the maturity of the cells. According to Cooke the length of life of a polymorphonuclear cell in circulation is about three weeks.

The steady state of the Arneth count.—The constancy of Arneth count in normal and pathological conditions is very remarkable. Ponder (1926) maintains that this constancy was the result of a balance between at least three factors—the production of the polymorphonuclear cells, their removal, and their development from class to class. He came to the conclusion that the distribution among the various Arneth classes was due to the cells remaining a short time in class I, a longer time in class II, a still longer time in class III and so on, the cells normally entering the circulation as cells of class I and leaving it from classes IV and V. The steady state in abnormal conditions, he thought, was due to the cells leaving the circulation from classes earlier than classes IV and V.

Influence of various drugs, organic and inorganic extracts, colloidal metals, ultra-violet and x-ray exposures on the Arneth count in experimental animals.

A shift to the left with thyroid and benzol has already been referred to. Ponder and Flint (1926) found that the removal of the thyroid in adult rabbits did not influence the Arneth count. They have shown that gelatin, trypsin, colchicin, nucleic acid, ether and thyroxin all deflected the Arneth count in the rabbit to the left and that pilocarpine had no effect. Each one of these substances deflecting the count produced at the same time a polymorphonuclear leucocytosis and they concluded that the substances deflected the count by stimulating the bone marrow and thus causing an outpouring of the younger forms of the polymorphonuclears, which have simple nuclear configuration.

Kennedy and Grover (1928) found that by a single exposure to x-rays the Arneth count in rabbits was deflected to the left. Kennedy and Thompson (1928 and 1929) found a similar shift to the left by an exposure to ultra-violet rays and by injections of various gonad extracts and of pituitrin, adrenalin and insulin. Danzer (1930) found that extracts of various organs and tissues when injected into rabbits deflected the Arneth count to the left, the deflection being due to the contained protein. The destruction and absorption of tissues *in vivo* was followed by a similar deflection. He thought that the deflection in the Arneth count after injury to various tissues might possibly be explained by that observation. He further suggested that the continual and normal break-down of tissue in the body was sufficient to provide a stimulus for the continual and normal output of polymorphonuclears by the bone marrow. Climenko (1930 and 1932) found that administration of irradiated ergosterol deviated the Arneth count to the left in the same way as an exposure to ultra-violet rays. He found that small doses of colloidal preparations of iron, cobalt, tin, copper, strontium, and nickel produced no significant deflection in the Arneth count. When these substances were given in doses from two to eight times greater than the minimum dose they produce a marked left-handed shift. Intramuscular injections of colloidal calcium and intravenous injections of calcium chloride also caused the count to be deflected to the left. He suggested that the effect of these substances was a non-specific one, due to a deviation in the normal concentrations of the inorganic constituents of the blood serum.

Clinical significance of the Arneth count.—The narrow limits within which the count varies in health has been alluded to. Most pathologic conditions which produce any change cause a shift to the left, that is, a

PLATE VII

Some of the nuclear formations met with in the cells
in various Arneith classes

high index. Cooke (1928) states that in all cases of microbic infection there is an increase in the percentage of the younger cells of classes 1 and 2, and a diminution in classes 3, 4 and 5. According to Cooke an increase in the cells of classes 1 and 2 above 40 indicates toxæmia.

That the Arneth count is deflected to the left in various forms of tuberculosis in man is well known. Ponder and Flint (1928) found that in experimental tuberculosis in the rabbit there was a left-handed deflection of the Arneth count, as in the disease in man. The deflection to the left is so constant in tuberculosis that some observers have come to the conclusion that the appearance of the deflection is diagnostic of the disease. Arneth—for example believed that this left-handed deflection occurred only in tuberculosis of active nature and in such cases alone, and when it occurred in other infections he thought that those infections were to be regarded as superimposed on a tuberculous basis; but Cooke (1914) showed that this view had no foundation and that the Arneth count could be deflected in a condition which had no tuberculous basis. He emphasized the occurrence of a left-handed shift as a constant occurrence in tuberculosis, but insisted that it was not characteristic of the disease alone. In tuberculosis the Arneth count was thought to be of great prognostic value, the higher the index the worse was the outlook thought to be. Arneth assumed that the cells with 1 and 2 nuclei were less resistant than the cells with 3, 4 and 5 nuclei and that when those less resistant cells were present in large numbers the severity of the case varied directly as the number of these cells. Hamilton-Black (1913) found that the phagocytic value against tubercle bacilli of the cells with 1, 2 and 3 and 4 nuclei was as 10 : 18 : 22 : 25. He observed that in certain cases of tuberculous disease tuberculin treatment improved the Arneth count making the shift to the left less marked. Holroyd (1913) studied the Arneth count in thirty cases of tuberculosis and arrived at the conclusion that in cases with unfavourable aspects the cells with one or with two nuclei were present in greater numbers than normally and that as the improvement in general condition took place the drift to the left of the picture was not so marked. Kennedy and Flint (1930) found that the Arneth count in cases of surgical tuberculosis treated by natural heliotherapy in the Alps did not show so great a left-handed deviation as in similar cases treated in Britain. They suggested that the fact might be taken as one of the indications of success of that method of treatment. This prognostic value of the Arneth count in tuberculosis has been very much disputed. As already mentioned, Ponder and Flint (1926) and Ponder (1928) could not confirm the findings of Hamilton-Black regarding the relation between phagocytosis and formation of the nucleus. They found that increase in nuclear lobulation which took place with increase of the age did not render the cell more active as a phagocyte.

A low index, i.e., a shift to the right occurs in pernicious anæmia. Fleming (1929) quoted a case of pernicious anæmia on treatment with liver extract, which showed an abolition of the marked shift to the right in the count, as the total blood picture returned to normal. When the liver treatment was stopped the polynuclear count moved over to the right and was again restored to normal by the liver treatment.

Egloff (1926) draws the following conclusions from his investigation on a shift to the right in the Arneth count.

(1) A shift to the right is observed in about 20 per cent of healthy persons and is a constant and stable characteristic for certain groups.

(2) In many sick persons a shift to the right is a constant phenomenon which may be indicative of certain diseases or functional conditions, perhaps an expression of diminished ability to react.

(3) This form of shift is apt to be encountered more often in stubborn and chronic processes.

(4) Under solar or serum therapy the tendency is to convert the shift to the right toward a shift to the left in connection with clinical improvement.

(5) In patients normally presenting a shift to the right, an active process is not always accompanied by a shift to the left.

The technique.—For the Arneth count scrupulously clean slides and thin well-stained films are essential. The slides should be put in sulphuric acid overnight and washed well in running water for four hours or longer to remove all traces of the acid. They are next washed in distilled water and then in alcohol and stored in absolute alcohol. At the time of using the slide is thoroughly dried with a piece of clean linen.

Leishman's and Jenner's stains are not satisfactory for the nuclei are poorly stained and the granules of the cytoplasm are too prominent. Giemsa or Wright's stains are quite satisfactory, but the stain which is strongly recommended and which we have found very satisfactory is hæmatoxylin and eosin—this stains the nuclear structure very clearly whilst the neutrophilic granules are not stained. The smear is fixed in methyl alcohol and stained with Delafield's hæmatoxylin solution for 3 to 5 minutes. The slide is washed well in water and as a counter-stain a 0.5 per cent solution of eosin is applied for a minute or so. The slide is again washed, dried and examined. In counting the number of nuclei in each cell Cooke's criterion should be kept in mind and the nuclear parts joined by more than a thread should be considered as one (see plate VII). Some experience is required in making the count because sometimes the lobes are lying in such a way that, although they may be separate, the whole looks like one convoluted lobe.

The normals.—Arneth gives the following figures as a normal count:

I	II	III	IV	V
5	35	41	17	2

If Cooke's criterion is adopted the normal reads as follows:

I	II	III	IV	V
10	25	47	16	2

The normal Arneth index (Bushnell and Treuholtz index) is about 60. In our work in asthma which we report below we have always made the count according to Cooke's method and have used the Bushnell and Treuholtz index (see page 257).

The value of the Arneth count in asthma

Not much attention has been paid to the Arneth count in asthmatic cases. Bray (1931) states that many observers during the crisis have recorded a change to the left in the Arneth count (Schiff noted this in thirteen out of fifteen cases) but he was not able to confirm this finding.

We have done the Arneth count in 143 cases of asthma, the results are tabulated in table I and above 70, out of 27 Gram-negative cases 19 have an index above 70, and out of 37 allergic cases

TABLE I
The Arneth indices in the three groups of asthma cases

Group	Total number of cases	Arneth index 60 and below	61-65	66-70	71-75	76-80	81-85	86-90	Above 90

20 cases, between 71 and 75 in 40 cases, between 76 and 80 in 21 cases, between 81 and 85 in 19 cases, between 86 and 90 in 17 cases, and above 90 in 8 cases. Taken as a whole these figures give no information of any value. When the cases are divided into the three groups suggested by us (the bronchial group, the Gram-negative-bacilli group, and the allergic group) we find that the Arneth index is usually high in the bronchial and Gram-negative-bacilli groups and usually low in the allergic group. If we take 70 as the dividing line we see that out of 79 bronchial cases 70 have an index

allergic cases (table II and graph II) we see that out of the sixteen cases in this group with an index of above 70, 14 cases belonged to the mixed bronchial and allergic type and only two cases to true allergic type. These two allergic cases had an index of 71, so that for practical purposes all the true allergic cases have an index below 70. If the 19 mixed cases (bronchial plus allergic) be taken out of the allergic group and counted with the bronchial group we find that out of 98 cases only 14 have an index of below 70 and 84 cases have an index above 70. Of the 18 true allergic cases only two cases had an index above 70 (71). This

TABLE II

and allergic cases be grouped together (table IV) we find that out of 125 cases only 22 cases have an index below 70 while 103 have an index above 70. By looking at table IV we can say that the asthma cases can be provisionally divided into two classes by means of the Arneth count—one class containing allergic cases in which the Arneth index will be 70 or

and allergic, and the Gram-negative-bacilli cases in which the Arneth index will usually be above 70. This latter class can be broken up into its component groups by means of the blood eosinophile count; we have shown in a paper which will shortly be published that the bronchial cases usually have a low eosinophile count; whilst the mixed bronchial and allergic

TABLE IV

Bronchial, mixed and Gram-negative-bacilli cases.	125	3	5	14	38	21	19	17	8
True allergic cases ..	18	4	6	6	2

cases, the Gram-negative-bacilli cases and the allergic cases usually have a high eosinophile count. So that in summarizing we can state that :—

(1) The allergic cases usually have a low Arneth index and a high eosinophile count.

(2) The mixed bronchial and allergic cases with the Gram-negative-bacilli cases have often a high Arneth index and a high eosinophile count. The Gram-negative-bacilli cases can be separated from the mixed allergic cases by the presence of the Gram-negative-bacilli in the sputum.

(3) The bronchial cases usually show a high Arneth index and a low eosinophilia.

Conversely :—

(1) An Arneth index of below 70 is found in the allergic cases; this is usually associated with a high blood eosinophilia, but occasionally there is a low blood eosinophilia.

(2) An Arneth index of above 70 plus a low blood eosinophilia is usually found in the bronchial cases and not often in the mixed bronchial and allergic cases.

(3) An Arneth index of above 70 plus a high blood eosinophilia is usually found in the Gram-negative-bacilli cases, and in the mixed bronchial and allergic cases.

The total leucocytes and the Arneth count.—Tables V and Va show the relation between the total leucocyte count and the Arneth count. Table VI shows the relation between the total polymorphonuclear count and the Arneth count.

There are two groups of cases placed within heavy lines in table V that require some further explanation.

The first group consists of 16 cases with a leucocyte count of 13,000 to 37,000 per cubic millimetre showing no appreciable shift to the left. In other words in these cases a high leucocytosis is associated with a more or less normal Arneth count.

The second group consists of 31 cases with a leucocyte count of below 8,000 per cubic millimetre, with the Arneth count showing an appreciable or a very marked left-handed shift. In other words in these cases a leucopenia is associated with a marked shift to the left.

(1) *A high leucocytosis without any appreciable shift in the Arneth count.*—Table V shows that in all there were 45 cases with a leucocyte count of above 13,000 leucocytes per cubic millimetre of the blood. Out of these 45 cases there were 16 which had an Arneth index of below 70. Reference to table Va (p. 264) shows that out of these 16 cases eight belonged to the allergic group, four to the Gram-negative-bacilli group, and four to the bronchial group. We have shown that allergic and Gram-negative-bacilli cases as a rule have a high blood eosinophilia, some of the bronchial cases also have a high blood eosinophilia and the four bronchial cases referred to happened to have a high eosinophile count, so that we see that all the sixteen cases in this group had a high eosinophilia. The high leucocytosis in these cases is due to an increase in the numbers of eosinophiles, the number of polymorphonuclears remaining the same. We have plotted the total polymorphonuclears against the Arneth index in table VI. If we take the normal number of polymorphonuclears to be roughly 70 per

TABLE V

36,000	1
37,000	..	1	1
	7	11	20	40	21	19	17	8	=143

cent of the total leucocytes then a count of 13,000 leucocytes will roughly contain 9,000 polymorphonuclears. In table VI we find that

sixty-nine, out of these 69 cases as many as forty-five had an Arneth index varying from 71 to 90, i.e., showing a marked shift to the left.

TABLE VI
Arneth index

Total polymorphs under	60 and below	61-65	66-70	71-75	76-80	81-85	86-90	Above 90	
2,000	3	1	1	1	..	6
3,000	2	4	1	1	2	3	3	..	16
4,000	1	4	3	8	2	1	2	2	23
5,000	2	1	4	7	4	1	3	2	24
6,000	2	3	1	4	1	2	13
7,000	1	1	2	5	4	2	4	1	20
8,000	3	3	3	1	10
9,000	1	1	1	4	2	2	2	1	14
10,000	1	1	1	1	1	..	5
11,000	2	2	..	1	5
12,000	1	1
13,000	1	1	2
14,000	1	1
15,000	1	1
16,000	1	1
17,000	1	1
18,000	1
19,000	1	1
20,000	0
	7	11	20	40	21	19	17	8	=143

there are 17 cases with a polymorphonuclear count of above 9,000 and that out of these cases there are only four with an Arneth index between 66 and 70, and the remaining 13 cases have an index varying from 71 to 90. This proves that a high leucocytosis combined with a low Arneth index means that the leucocyte increase is due to an eosinophilia.

(2) *The association of leucopenia with a high Arneth index, i.e., a marked shift in the Arneth count to the left.*—Table V shows that there were thirty-nine cases of this group who had a total leucocyte count below 8,000 per cubic millimetre of blood, out of these cases as many as thirty-one had an index of 71 and over. A reference to table Va shows that of these thirty-one cases, twenty belonged to the bronchial group, six to the Gram-negative-bacilli group, and five to the allergic group (these five cases were mixed bronchial and allergic cases). So that all the thirty-one cases in this group were associated with infection. Usually with a shift in the Arneth count to the left, i.e., with an active bone marrow we would expect to get a leucocytosis in the blood. In order to rule out the possibility of the leucopenia in these cases being due not to a decrease in the number of the polymorphonuclears but to a decrease in the other types of cells we have plotted the total polymorphonuclears against the Arneth index in table VI. If we take 5,000 polymorphonuclears in one cubic millimetre of blood to represent roughly the normal figure we see in table VI that the number of cases who had a polymorphonuclear count of below 5,000 was

So that we see that in these cases there is a polymorphonuclear leucopenia and yet a shift in the Arneth count to the left indicating that in spite of the reduction of polymorphonuclear cells in number—young forms are in preponderance.

Cooke (1928) maintains that in all cases of microbic infection there is a left-handed shift in the Arneth count whether the total polymorphonuclears remain normal in number, whether there was a polymorphocytosis or whether there was a polymorphopenia. A shift to the left in the Arneth count with a polymorphopenia therefore must mean that the activity of the bone marrow cannot keep pace with the destruction of these cells. In the tropics many of these cases are subjects who have malaria, kala-azar or hookworm infections.

Piney (1927) is of the opinion that when an infection is intense it depresses the bone marrow and causes a neutrophile leucopenia instead of the usual neutrophile leucocytosis, the latter is characterized by a shift to the left in the Arneth count. In those cases where there is a neutrophile leucopenia with a shift to the left in Arneth's count he considers that there is some toxic agency causing a complete alteration in the process of maturation of the neutrophilic cell.

Ponder (1926) stated the equilibrium in the percentage of cells in the various Arneth classes was in no way dependent on the number of

cells in the blood stream. The only essential thing for this equilibrium is that the number of cells entering the circulation be equal to the number leaving it. He discusses all the possible combinations between the rate of production of the polymorphonuclear cells and their removal from the blood stream.

TABLE Va
Arneth index

Total leucocytes under	60-Below	61-65	66-70	71-75	76-80	81-85	86-90	Above 90
5,000	1				1	2		1
6,000		1		1	1	2	1	
7,000			1	2		1	2	
8,000		1		1	4	1	1	2
9,000	1		2	2		1	2	1
10,000		2	2	1	1	2		1
11,000	2		2	7	3	2	2	
12,000	1			1		1		
13,000		2		1		1	2	
14,000	1	1	1	2	5			
15,000			1	2		1	3	
16,000		1	1	2	1	1	3	
17,000			1					1
18,000	1			1				
20,000			1		1	1	1	
23,000						1		
25,000			1					1
26,000				1		1		
36,000		1						
37,000								

1. (ordinary type)=Bronchial cases.

11. (out-lined figures)=Gram-negative-bacilli cases.

1. (bold-face figures)=Allergic plus bronchial and allergic cases.

We can thus appreciate (a) why a leucocytosis with a normal or sub-normal Arneth's count is seen in asthmatics—and it is due to a

high eosinophilia, and (b) why, when there is a leucopenia, there is still a shift to the left in the Arneth count.

NOTES ON BERBERINE SULPHATE IN ORIENTAL SORE

By E. W. HAYWARD, M.A. (Cantab.), F.R.C.S. (Edin.),
L.S.A. (Lond.)

Principal Medical Officer, Jodhpur State, Rajputana

DURING the last few years a number of papers on the treatment of oriental sore by berberine sulphate have appeared in the *Gazette*. As in most instances only a small number of cases have been reported upon, it was suggested to the writer that in Rajputana, where the disease is endemic, it might be possible to collect notes of the results of treatment in a large series of cases.

Berberine sulphate has been used as one of the standard treatments for oriental sore for the last two years. The method adopted has been that suggested by Das Gupta (1930), namely, the impregnation of the sore and the tissues immediately adjacent to it, both at the base and around the edges, with a one or two per cent solution of acid berberine sulphate.

The details that it has been possible to collect are regrettably incomplete. It is almost impossible, even in big hospitals, for medical officers to keep detailed notes of out-patient treatments, in view of the mass of work which each man has to get through, often under very unsatisfactory conditions as regards accommodation; the same remark applies even more forcibly in country districts, where there is one doctor to 100,000 people spread over an area of 2,000 square miles.

Again, it will be seen that the majority of the cases are diagnosed clinically. It is of course very desirable that in every case the diagnosis should be confirmed by microscopical examination, but this is a degree of perfection that it is almost impossible to achieve under the present conditions. However, the sore has certain very marked characteristics with which medical officers working in an endemic area are usually familiar. A negative finding is by no means conclusive evidence against the diagnosis of oriental sore; therefore the finding of leishmania in about one in four of the State hospital cases suggests that a very large percentage of the cases are really oriental sore.

The details collected from three sources are given below.

District dispensary cases

Thirty-nine patients were treated, 3 on positive laboratory diagnosis and 36 on clinical diagnosis, with complete cure in all cases. One hundred and seventy-five injections in all were given, the average being therefore $4\frac{1}{2}$ injections per patient.

In 8 more clinically-diagnosed cases, a total of 26 injections was given; these patients showed definite improvement but failed to complete the course of treatment.

In 14 other cases, 24 injections in all were given, but as the patients did not attend again no prognostic observations were made.

City dispensary cases

Fifty cases, diagnosed clinically, were all reported cured after an average of 5 injections each. No details are obtainable.

State hospital cases

Three hundred and ninety-eight cases were examined microscopically; in 140 of these leishmania was found. Of the 398 patients, 264 consented to injections being given; these included 79 cases in which leishmania had been found, the remainder being clinically diagnosed.

In all 611 injections were given as follows:—

Cases in which 1 injection was given ..	132
" " " 2 injections were given ..	51
" " " 3 " " " ..	35
" " " 4 " " " ..	14
" " " 5 " " " ..	13
" " " 6 " " " ..	11
" " " 7 " " " ..	2
" " " 8 " " " ..	1
" " " 10 " " " ..	1
" " " 13 " " " ..	3
" " " 14 " " " ..	1

All those who received five or more injections were definitely cured. Those who received three and four all showed some improvement. Of those who only attended once, nothing more is known, and nothing definite can be said of those who only attended twice.

The above records are of only limited value, in my opinion, but they indicate that the injections are sufficiently painful to drive a very large number of patients away.

However, educated patients, who understand the necessity for the injections, and patients that can be persuaded by the local doctor, who in country districts is often in close touch with the people, continue the treatment and reap the benefit, as it would appear that, if persevered with, berberine sulphate injections are a certain cure in cases of oriental sore and also possibly of other sores.

Punjab Civil Medical Service

An epidemic of cerebro-spinal meningitis broke out in the Borstal Institution, Lahore, suddenly during the spring of 1932. The first two cases occurred on 12th March and cases continued to occur at varying intervals right up to the middle of June, a total of eighteen cases

in all. Subsequent to this no cases occurred for a period of about two and a half months, when suddenly at the end of August there was a fresh outbreak with four seizures up to the date of this report, November 1932.

Before giving a description of the various features of the epidemic it would be useful to give brief information about the conditions prevalent in the institution prior to the outbreak of the epidemic. This institution is primarily meant to accommodate adolescent and juvenile offenders. The designed accommodation provided is for 1,705 inmates. Out of these 350 inmates live in 'association barracks' and the remainder in single cells.

The actual population at the time of the outbreak was 1,721, and for the preceding four months it had ranged between 1,800 and 2,489. About the middle of November 1931, owing to the Ahrar movement, a very large number of prisoners were received for admission in this institution; these had been evacuated from various camp jails of Kashmir State, *e.g.*, those at Satwari, and Udhampur. Though no authentic information is available of the occurrence of any case of cerebro-spinal fever in the camp jails in Kashmir, which were seriously overcrowded at the time for unavoidable reasons, yet some of the prisoners received from there mentioned the occurrence of an illness somewhat similar in nature to the present seizures. It is quite possible that the overcrowding in these camp jails may have led to an increase in the percentage of carriers amongst the population confined therein. The present epidemic in the Borstal Institution may be the direct outcome of increase of carriers brought about by the arrival of a large number of carriers amongst the prisoners received from the Kashmir State.

Mode of spread

The first two cases occurred amongst the inmates working in the kitchen, and at intervals isolated cases cropped up like mushrooms with surprising suddenness from different circles and barracks. It was very difficult to establish the connection of one case with another; while one inmate fell a prey to the disease his close associates entirely escaped. The disease in most cases picked out those inmates that were apparently healthy and well nourished. None of the established carriers (detected by examination of throat swabs) and none of the hospital staff or attendants contracted the disease.

Signs and symptoms

Out of the twenty-two cases that have occurred up to date five were of the fulminating type, and the rest may be labelled as of acute type. A brief description of each type is given below.

Fulminating type.—Cases of this type when brought to the hospital were invariably unconscious and deeply comatose. History was forthcoming from the comrades of the patient that he had been complaining of slight headache and slight fever prior to unconsciousness. The patient kept in a state of active delirium, very restless, giving forth every now and then a short monosyllabic cry. The eyes were rolled up with corneæ insensitive and with reflexes, both superficial and deep, invariably lost. Incontinence of urine and faeces was present in most of them. Rigidity and Kernig's sign were absent. Limbs were flaccid. Cerebro-spinal fluid was slightly purulent in some cases, and in others it was so thick that it could hardly be drawn. These patients invariably died, the whole course of the disease lasting a few hours.

Acute type.—Patients on admission complained of fever with rigors, severe headache, vomiting, rigidity of the neck, etc. One noticed impaired mental condition in most of them. They were dull and apathetic, and their reflexes both superficial and deep were either totally absent or sluggish. Some of the patients had marked hyperæsthesia; so much so that they gave forth a sharp cry whenever they were touched.

Two cases exhibited very mild features. There was complete absence of any abnormal mental conditions, and pyrexia was slight and of short duration. The only sign noticed was rigidity of the neck.

It will be useful to put down for information the salient features of the various signs and symptoms observed in these cases.

Fever.—The pyrexial period varied from four days in one case to twenty-six days in another, the average being twelve days. In many cases there was a recurrence of temperature after several days of apyrexia and in most of the cases this coincided with some complication, such as affection of the joints. No special peculiarity has been noticed as characteristic of this disease. Fever charts of a few cases are given on page 269.

Rigidity of neck and back.—This was a marked and common feature found in practically all cases excepting the fulminating type. The degree of rigidity varied in different cases; in the majority of cases it was simply complained of as stiffness of neck or muscles of the back. In two cases it was of extreme severity, the patients being practically rigid like a board and in an opisthotonic condition for a period of forty-eight to seventy-two hours. Repeated drawings of cerebro-spinal fluid afforded relief in a large number of cases, but made little or no difference in severe cases.

Headache.—Headache in varying degrees of severity was complained of in all cases. A history of the presence of headache was obtainable in all the cases before the onset of other symptoms; in some cases it was complained of as lancinating in character. Repeated lumbar punctures gave considerable relief. Persistence

of headache for several weeks even after apparent recovery was a common feature in all cases.

Herpes.—Herpes developed in 50 per cent of cases; in all the cases it was extensive. In seven cases it involved the area of lips and cheeks and in two it appeared on the sides of chest. It usually appeared about the end of the first week but in some cases as early as the second day of illness.

COMPLICATIONS

Joint affections.—This complication arose in four cases of the series during the second week of the illness. Two cases showed involvement of knee joints with a good deal of effusion in the synovial cavity accompanied by other signs very much like acute arthritis. The fluid aspirated from the knee joint was a pale exudate, thick and gelatinous in character. Microscopic examination revealed the presence of a large number of pus-cells but no meningococci. Cultures from the joint effusion were reported to be negative for meningococci. In the other two cases the affection consisted of acute arthralgia of the knee.

In cases of involvement of the knee joint accompanied by effusion, repeated aspirations and injections of 10 cubic centimetres of anti-meningococcus serum into the joint resulted in rapid improvement and disappearance of symptoms.

Hemiplegia.—This occurred in one case only, on the 12th day of the disease. The right upper and lower extremities were both involved. It was not progressive but came on suddenly. This patient eventually died three days after the appearance of paralytic symptoms.

Diplopia.—This was observed in one case only. It occurred on the twenty-sixth day of illness, viz, during convalescence. It lasted for eight days and then gradually disappeared altogether.

Pneumonia.—This occurred in one case only. It was of the lobar type, and appeared on the second day of the illness; it proved rapidly fatal, the patient dying on the same day.

Diagnosis

In an institution with a population of about 1,700 inmates it was very important to discover and diagnose cases of cerebro-spinal fever as early as possible, both with a view to arresting the further spread of the epidemic, and to giving early treatment, thereby increasing the chances of recovery. Cases presenting even the slightest signs clinically were promptly segregated in a separate hospital reserved for them inside the institution. To achieve the object of early diagnosis, the following procedure was adopted as a routine in examination of the cases:—

Blood examination.—Blood films of all such cases that were admitted in the institution hospital with pyrexia were carefully examined with a view to detecting the presence of (a) any

blood-parasites and (b) a polymorphonuclear leucocytosis. Cases which presented a blood picture of polymorphonuclear increase to 80 per cent or more were marked for special observation for any subsequent development of clinical signs, e.g., headache, rigidity of the neck, or Kernig's sign. This procedure was found a good aid to early diagnosis of cases.

Lumbar puncture.—This was performed in all cases whether clinically positive or suspicious. In cerebro-spinal-fever cases the fluid came out under great pressure and was turbid—the turbidity varying from slight opalescence in less severe cases to a purulent exudate in the fulminating cases. It is interesting to note that in one fulminating case from the very beginning no cerebro-spinal fluid could be drawn in spite of repeated punctures; this patient died within a few hours. In two other cases failure to draw any fluid from the cerebro-spinal canal occurred at a later stage of the illness. Microscopic examination of cerebro-spinal fluid invariably revealed the presence of enormous numbers of polymorphonuclear leucocytes and a few intracellular diplococci morphologically indistinguishable from meningococci. A specimen of the same fluid drawn was sent for cultural examination to the bacteriological laboratory of the King Edward Medical College, Lahore, which reported the results as 'positive', in all cases. All the specimens of cerebro-spinal fluid in positive cases showed absence of glucose and increase of albumen.

Pathological autopsies

Out of eleven patients that died of cerebro-spinal fever, three were sent to the King Edward Medical College for post-mortem examination. For detailed post-mortem reports see appendix.

TREATMENT

Serum therapy.—Immediately a case was diagnosed as cerebro-spinal fever, anti-meningococcus serum (20 to 30 c.cm.) was administered intrathecally and about 10 to 20 cubic centimetres intravenously. In all the acute cases intrathecal administration was repeated practically every twenty-four hours, until the patient's condition showed improvement and the cerebro-spinal fluid was found to be free from meningococci.

The two indications taken as guiding factors for further administration of serum were (a) the patient's general condition and (b) the condition of the cerebro-spinal fluid. Mere opalescence or slight turbidity of the cerebro-spinal fluid was not considered a sufficient indication for a further dose of serum. Administration of serum was suspended only at the stage when the cerebro-spinal fluid showed absence of meningococci and a return of the presence of sugar. On an average 100 to 150 cubic centimetres of anti-meningococcus serum per head was found to be sufficient in our cases;

the maximum amount of serum required in one case was 225 cubic centimetres.

Lumbar puncture

Lumbar puncture in addition to being a necessary concomitant of intrathecal administration of serum was performed whenever the necessity arose for relieving the pressure symptoms. The quantity drawn at each sitting varied in different cases; in one case 95 cubic centimetres of cerebro-spinal fluid was drawn at one sitting alone. During the course of treatment dry punctures were met with in three cases. In one case after successive dry punctures on three consecutive days, there was a return of cerebro-spinal fluid on the fourth day. This patient is still under treatment and is doing well.

Prophylactic measures

While devising and putting into practice the measures to combat the propagation of this disease one had to keep in view the fact that the meningococcus is an inhabitant of the nose and nasopharynx, that the disease is by droplet infection, and that for all infections of this sort a close contact is generally necessary as the meningococcus is an organism of very low vitality which cannot stand the extremes of temperature, daylight, or desiccation for long, and whose life outside the body is amazingly short. The delicacy of the organism strongly suggests that the disease is spread directly from an individual who is harbouring the virus whether he be a patient suffering from the disease, a mild abortive case going about unnoticed in the community, or a carrier. Keeping the above facts in view the following prophylactic measures were carried out:—

Isolation of the sick.—All cases of cerebro-spinal fever were promptly isolated in the hospital in the new section of the Borstal Institution, so that there was no chance of anybody having access to them except the hospital attendants.

Segregation of the contacts, and carriers.—The contacts of these cases were promptly segregated and each of them was kept in a separate cell. Their throats were examined to detect carriers among them. During the day they were made to work in the open air and every contact was under the close observation of the medical staff.

The nasopharynxes and throats of all the inmates, including the contacts, were examined and swabs taken to detect carriers of meningococci amongst them. The carriers were kept separate from the others and were made to work in the open air during the day-time. They too were under close observation of the medical staff.

To detect new cases as early as possible all the fever cases were examined twice daily, in the morning and evening, and instructions were issued to bring promptly to the notice of the medical staff any patient complaining of severe headache, fever, catarrh, etc.

Avoidance of overcrowding.—Existing berths in the association-barracks being considered too close to each other in most cases, it was ordered that the inmates should sleep on alternate berths. They were advised to sleep with their heads against the iron gratings to get more fresh air.

Overcrowding was avoided in the workshop by keeping the men sufficiently apart from each other and making them work as far as possible in open air.

School classes were held in the verandahs or open air.

Prisoners working in the kitchens were gradually replaced and put on outdoor work.

To reduce the humidity of the cells and barracks all *lipai* and *pocha* was prohibited.

Disinfection of clothing and equipment of the inmates

All the blankets and clothes were disinfected by passing through a pressure steam sterilizer.

All blankets and mats during the day were spread out in the sun.

Chlorine solution was supplied to enable the inmates to soak their safas in it, as these are usually used as towels for cleaning their noses.

The use of common drinking vessels by prisoners was strictly prohibited.

Lectures were delivered to the inmates on the importance of scrupulous cleanliness of their persons and clothing, and on the dangers of haphazard spitting, sneezing and coughing in presence of other inmates.

Phenyle cups were provided in the institution at various places, and the importance of spitting into them *only* was impressed on the inmates and the staff.

Gargling parades were held at lockout and lockup time to administer Condyl's fluid as gargles to the inmates.

Visitors were reduced to a minimum, and the interviewers were made to interview the prisoners at a distance of at least three feet from them.

Admissions to the institution were stopped for the epidemic period.

In addition to the above measures the general sanitation of the institution was scrupulously looked after and every barrack and cell was whitewashed and disinfected.

I. A fatal case.
(T = turbid; P = purulent).

II. A fatal case.
(T = turbid).

III. A non-fatal case.
(T = turbid; C = clear).

APPENDIX

Autopsies

Case 1. Nervous system.—The sub-arachnoid in the entire cerebro-spinal axis full of yellow pus. No distension of ventricles. Pus showed Gram-negative diplococci resembling the meningococcus.

Respiratory system.—Both lungs showed parietal adhesions. Left lower lobe collapsed and firmly adherent to chest wall. It had to be torn away piecemeal in removal. Trachea congested.

Abdomen.—Slight enlargement of mesenteric lymph nodes. Gastric mucosa acutely congested. Mucosa of intestine congested with submucous hæmorrhages at places.

Spleen.—Enlarged. Acutely congested causing a diffuent condition of the pulp.

Liver.—Showed yellow areas of necrosis.

Kidneys.—Acutely congested.

Case 2. Nervous system.—Marked congestion of superficial blood vessels. A purulent exudate at the base and on the posterior aspect of the spinal cord. Ventricles greatly distended with turbid fluid as the result of

internal hydrocephalus. Smears from pus showed meningococci.

Kidneys.—Hyperæmic.

Case 3. Nervous system.—Intense engorgement of surface blood vessels. No sub-arachnoid accumulation of the pus on vertex. Marked degree of purulent meningitis at the base. Pus smears from the base showed intracellular diplococci in a predominantly polymorphonuclear exudate.

Respiratory system.—Left lung showed firm parietal adhesions. Hypostatic congestion in both lungs.

Circulatory system.—Pericardium contained about three ounces of hæmorrhagic effusion. Heart flabby. No gross surface abnormality.

Abdomen.—Two areas of submucous hæmorrhages in the intestine, one high up in the ileum, the other in ascending colon.

Spleen.—Enlarged. Trabecular hypertrophy. Diffuent owing to decomposition.

Liver.—Atrophied. Surface mottled but smooth. Section showed numerous regenerating nodules as seen in toxic cirrhosis.

SPINAL PERCAIN ANÆSTHESIA

By T. H. SOMERVELL, M.B., B.Ch., F.R.C.S. (Eng.)
*South Travancore Medical Mission, L. M. S., Neyyoor,
 Travancore, South India*

PERCAIN, a derivative of quinoline, is far more powerful in its action than any of the cocain and novocain group of drugs, and, though it is also far more toxic, its toxicity does not matter for practical purposes, owing to the extreme dilution in which it is used for spinal anæsthesia.

A preliminary injection of morphia (1/6th to $\frac{1}{4}$ gr.) and liyoscine (1/150th gr.) should be given half an hour or so before the spinal anæsthetic is administered. In a very nervous patient a light chloroform anæsthesia can be given for the spinal injection, or the skin over the lumbar spines can be rendered anæsthetic with novocain.

A solution of 1 part of percaïn in 1,500 parts of 0.5 per cent sodium chloride is used. This solution must be sterilized and tested with litmus or phenolphthalein, and if it is alkaline it must be neutralized with a drop or two of dilute hydrochloric acid, as it does not keep in an alkaline solution.

The syringe for its use, together with the spinal needles, must be washed out with sterile distilled water, or a precipitate will form. An average dose is 9 c.cm. of this solution, and it is injected fairly rapidly into the cerebrospinal canal at the level of the interval between first and second, or second and third lumbar vertebræ, the patient lying in the usual position on the side with head and knees approximated so as to arch the back.

Owing to the solution (specific gravity 1003.5) being lighter than cerebrospinal fluid (specific gravity 1005.5) the patient must at once be placed in the ventral decubitus on a flat table, with the head slightly inclined downwards projecting over the end of the table. The patient must remain in this position until sensation is absent up to about the level of the seventh or eighth dorsal nerves; this may take from six to ten minutes. He is then turned into the position of dorsal decubitus, the head still being kept low. The operation may now begin.

A considerable lowering of the blood-pressure will by this time have taken place, but although this may be restored by the injection of advenalin or ephedrine, we have found it in almost every case quite unnecessary to do this. Patients have remained throughout a long operation with a blood-pressure of between 40 and 60 millimetres of mercury without any apparent ill-effects, and we now hardly ever take any notice of the blood-pressure, though the anæsthetist ought to feel the pulse from time to time as a precautionary measure.

The operation can be performed with an almost total absence of shock, a very striking absence in big operations, such as abdomino-

perineal cancer of rectum, Wertheim's hysterectomy, or gastrectomy.

For gastrectomy we usually give a splanchnic anæsthetic as well, as soon as the abdomen is opened, injecting 30 cubic centimetres of 0.75 per cent novocain into the prevertebral space at the level of the first lumbar vertebra. The immediate effect of this is to raise the blood-pressure, sometimes almost to the normal. Moreover it prevents the reflex retching and vomiting which otherwise may occur when the stomach and upper abdominal viscera are manipulated.

The anæsthesia is usually complete for some two hours, though the time varies considerably and may be as long as three and a half hours. For this reason, the patient when put back to bed should have his head kept low, without a pillow, and the foot of his bed raised six inches or so until three hours after the end of the operation.

We have done at Neyyoor some one hundred and fifty cases by this method of anæsthesia during the last few months, and now use it invariably for all operations on the abdomen and most others on the lower half of the body. Complications are usually of little significance, and may be tabulated as follows, in order of frequency.

(1) Rise of temperature varying from 1° to 6° (or in one case 7°), lasting a few hours, and of no apparent influence on the patient's recovery and convalescence.

(2) Headache, beginning a few hours after the operation, and lasting for a time varying from three hours to three days. Usually the headache is slight, but in three or four cases it has been severe, and in one case it was very severe indeed.

(3) Restlessness, lasting one or two days, in six cases of our series. In only two cases was this serious, and both of them recovered without any further mishap.

Beyond these we have not seen any complications at all. But doubtless if the head and neck are not kept low we would have had to record failure of respiration. The lower intercostal muscles are of course paralysed in every case, but the diaphragm makes up for their inaction; it is however important to take postural precautions that the diaphragm be not paralysed.

The absence of irritating effects on the lungs is an important advantage of this method of anæsthesia; but the most striking benefit from its use is the total absence of vomiting after abdominal operations. Percain anæsthesia enables big operations to be performed in cases that are otherwise inoperable or desperate, with a minimum of risk; and we have often been surprised at the extreme fitness of patients after extensive operations. It is no exaggeration to say that a gastrectomy with percaïn anæsthesia gives us less trouble and anxiety after operation than a gastro-enterostomy used

to do with inhalation anæsthesia. I recently did a perineal excision of a rectum in which the patient was as fit after the operation as is the average case of hydrocele. Another great advantage of percain anæsthesia is the excellent relaxation of the abdominal muscles, which renders closure of the wound extremely easy, and exposure of the viscera is far more readily obtained than it ever is with even the most skilfully administered inhalation anæsthetic. A short time ago I removed an appendix through a gridiron incision with no assistance and no anæsthetist, and nobody to hand instruments or thread needles, in less than a quarter of an hour. I found the retraction of the muscles and the subsequent closure of the wound very easy to do. I do not recommend this procedure to any surgeon, but it shows what percain can do, and suggests its utility in an emergency when sufficient help is unobtainable or where the technique or sterility of assistants cannot be trusted.

A word of warning must be given with regard to failure to produce anæsthesia. This has happened several times in our series, but in only one case has it occurred where the cerebrospinal fluid dropped freely from the spinal needle on insertion. If the flow of fluid be not free, or if the fluid is stained with blood, it is probable that the opening at the point of the needle is only partially in the subarachnoid space. The remaining part may be between the dura and arachnoid membranes (in the subdural space) or leading into a blood-vessel. In these circumstances only a portion of the percain solution will be injected subarachnoidally, the remainder having no anæsthetic effect. And of the failures to produce anæsthesia which we have seen, this was the apparent reason in every case except the one already mentioned. It may therefore be taken as practically universally true that every case in which a satisfactory flow of clear cerebrospinal fluid is seen through the needle before the injection is done will be successfully anæsthetized by percain, provided the technique is carried out as described, and the right amount of the solution injected. For an average adult male, 9 to 10 cubic centimetres are sufficient to produce anæsthesia up to the sixth dorsal nerve. Short patients require less (7 c.cm. or so) and patients with a very long vertebral column may require up to 11 cubic centimetres.

In conclusion, it may be said that percain spinal anæsthesia as described is as far as is at present known the ideal anæsthetic for all abdominal and lower extremity operations, is pleasant for both the patient and the surgeon, and reduces the distress from vomiting and the risks from other complications to the minimum to which modern science can at present reduce them.

The analysis of one hundred consecutive cases shows the following figures :—

Headache was severe in two, bad in nineteen, slight in sixteen, and absent in sixty-three cases.

Restlessness was severe in one and moderate in three cases.

Shock occurred in two cases.

Pneumonia followed in seven cases (all this series were done at a bad time of year for pneumonia).

Vomiting after operation in five cases, two of which were abdominal cases.

Drop in blood-pressure.—The largest falls were from 110 to 30 millimetres, *i.e.*,—80 millimetres, and from 140 to 50, *i.e.*,—90 millimetres; the average was 42 millimetres in the whole series.

Failure.—Percain failed to act, though cerebrospinal fluid was freely obtained, in one case.

Deaths.—None were directly due to percain. One patient died of anæmia and one of uræmia, each four days after operation; one died of dysentery, fourteen days after operation.

Operations represented

Gastro-enterostomy	..	52
Gastrectomy	..	9, with one death.
Appendicectomy	..	8

OBSERVATIONS ON AN EPIDEMIC OF WHOOPING-COUGH AT THE LAWRENCE ROYAL MILITARY SCHOOL, SANAWAR

WITH A NOTE ON THE INVESTIGATION OF A SKIN REACTION IN THIS DISEASE

By C. F. J. CROPPER, B.A. (Oxon.), M.R.C.S., L.R.C.P.
CAPTAIN, I.M.S.

and

JEMADAR MILKHI RAM, I.M.D.

(*The Lawrence Royal Military School, Sanawar, Simla Hills*)

THE following observations were made on a series of 25 cases of whooping-cough occurring at the Lawrence Royal Military School, Sanawar, between 29th July and November 1932.

Previous epidemics

It will be of interest first to tabulate the month of the year in which previous epidemics of whooping-cough in this school commenced :—

TABLE I

1897 .. January	1912 .. May	1929 .. March
1898 .. July	1913 .. March	1930 .. May
1905 .. April	1914 .. February	1932 .. February
1907 .. June	1915 .. March	1932 .. July

This table shows that there is no very definite seasonal incidence.

The present epidemic

In the epidemic under consideration, the infection was brought to the school from Kasauli by a member of the boys' department, where three further cases occurred. One of these patients transmitted it to the preparatory department which he was attending daily for class-work, here it spread extensively, though no further cases occurred in other departments. (This chain of infection is a good illustration of an important axiom of school-hygiene, viz, that the separate departments in a large school should be kept as isolated as possible from each other.) One case occurred in a sweeper's child.

The preventive measures adopted consisted of:

- (a) Complete segregation of all four departments.
- (b) Lessons in the preparatory department being conducted in the open air.
- (c) The use of 'Izal' disinfectors, especially in chapel, which was attended by both boys and girls.

It was impossible to attempt to isolate children in the preparatory department in the catarrhal stage, practically all of them having coughs owing to the wet weather.

Mode of infection.—The mode of infection is shown by the following table:—

TABLE II

Infected from dormitory neighbour	.. 1
Infected from class neighbour	.. 7
Infected from playmate	.. 13
Infection not directly traceable	.. 4

This table shows the importance in epidemics of finding out from house-masters, etc., the names of the friends of infected children.

Incidence.—Among the cases in the preparatory department, where both sexes were equally exposed to infection, 13 boys and 7 girls were affected. No true deduction can be made regarding age incidence, as the majority of the cases were amongst children of a selected age. Weakly children and those with unhealthy tonsils did not appear to be especially prone either to infection or to severe attacks.

Characters of the epidemic.—The average whooping period was found to be 13.52 days; the longest period was 46 days, whilst in three cases no whooping occurred, the diagnosis depending on the occurrence of a catarrhal stage followed by vomiting.

Vomiting occurred at some stage in every case; in nine cases it preceded the whoop by one to eight days, and in six cases it outlasted the whooping stage by one to eight days. In ten cases the temperature reached 100°F. or over, three of these being weaklings. In ten cases, rales were noted in the chest.

Relapses occurred in six out of twenty-five cases, three patients having a double relapse.

One relapse was characterized by vomiting only. Five out of the nine relapses occurred shortly after a heavy fall of rain (2.5 inches), when the humidity was high and there was little sunlight for the patients to play in.

The following complications were noted: broncho-pneumonia (1), otitis externa (3), pyelitis (1), tonsillitis (2), severe sub-conjunctival hæmorrhage (1), and prolapse of rectum (1). The last is better described as a sequela. It occurred during the third short relapse in a debilitated patient, aged 3.

There is little doubt in the writers' minds that, in the light of the epidemic under review, a progressive immunity develops in a group of individuals exposed to infection, and that immunity to whooping-cough can be acquired without the individual necessarily suffering from any symptoms. The reasons for this conclusion are as follows:—

(1) The whooping stage towards the close of the epidemic became far shorter than the average; in the last four cases it was absent in two, and lasted one and two days, respectively, in the other two.

(2) Among four nurses, aged 17 to 19, who had not had whooping-cough and who were in close contact with the patient, none developed the disease.

The conclusion of most observers, that the period of infectivity is practically confined to the catarrhal stage, was borne out in this epidemic, although all cases were isolated for at least six weeks.

Treatment.—An accurate appreciation of the value of treatment in whooping-cough is admittedly impossible. Is the length of the whooping stage a satisfactory criterion? It varies from case to case apparently without rhyme or reason. However, like other observers in this field have done before us, we yield to the temptation to summarize results in a table, the limitations of which are self-evident.

TABLE III

Method of treatment	Number of cases treated	Average duration of whoop
Ephedrine	4	4.2 days.
Belladonna	9	6.6 "
Belladonna and vaccine	6	18.6 "
Ephedrine and vaccine	4	22.7 "
Belladonna and adrenalin	2	29 "

A word of explanation is necessary; ephedrine treatment consists of ephedrine hydrochloride (P. D. & Co.), gr. 1/2, three times a day for a child of 6 years, reducing the dose if sweating or flushing occurs; belladonna treatment consists of increasing doses of the tincture in a sedative expectorant mixture, until marked dilatation of the pupil occurs; vaccine treatment consists of hypodermic injections of 'Pertussis

Immunogen (Combined)', (P. D. & Co.), rising from 0.2 c.cm. to 0.8 c.cm. for a child of six years; and adrenalin treatment consists of adrenalin hydrochloride, minims iv, four times a day.

The superior efficacy of ephedrine in the above table is only apparent, as three of the four cases were the last three cases in the series. As regards the vaccine treatment, it is a curious, but perhaps not significant, fact that five out of the six relapse cases were treated with the vaccine.

It will be observed that no mention has been made of the well-known rectal ether medication. This was given a trial during the third relapse in a girl aged six. Ether was administered for a full week in the orthodox manner, but the whoop did not decrease at all.

In one case refractory to treatment, the Sister administered a stern rebuke, with immediate curative effect.

Summary of treatment.—The conclusion is unavoidable that none of the methods used in this epidemic appeared to stand the test of practical experience. Are the encouraging results reported by some observers, due to the character of the epidemic, and not to the treatment at all?

This question forced itself upon the writers when faced with the more baffling and refractory cases.

The skin reaction.—At the suggestion of Lieut.-Col. J. A. Sinton, V.C., I.M.S., the possibility of there being a skin reaction to determine susceptibility to whooping-cough, on the analogy of the Schick reaction, was investigated.

The antigen used was 0.02 c.cm. of 'Pertussis Immunogen' (P. D. & Co.) diluted to 0.2 c.cm. with normal saline. For the controls, a similar dosage of vaccine, after being heated to 75°C. for 10 minutes, was used. Preliminary trials pointed to this dosage as being suitable.

The children selected were girls between the ages of 14 and 17, of whom 26 had had whooping-cough ('theoretical immunes') and 33 had not ('theoretical susceptibles'). The following table shows the results obtained:—

TABLE IV

	Theoretical immunes	Theoretical susceptibles
Control and antigen reactions equal.	13 out of 26	12 out of 33
Control reaction exceeded the antigen.	9 out of 26	3 out of 33
Results analogous to 'Schick'	6 out of 26	9 out of 33

The table shows that, judging from the large percentage of anomalous results, there is no skin reaction in whooping-cough analogous to the Schick reaction in diphtheria.

(Continued at foot of next column)

'NOVOSTIBUREA' IN THE TREATMENT OF KALA-AZAR

By S. N. SUR, M.B., D.P.H. & D.T.M.

Assistant Director of Public Health, Malaria Research and Kala-Azar Survey, Bengal

and

S. K. NEOGI, B.A., M.B.

THE success of pentavalent organic compounds of antimony in the treatment of kala-azar has led investigators to search for new and more advantageous compounds in the field of organo-metalloid compounds. The well-known compounds—urea stibamine and aminostiburea—though they have many advantages over the simpler antimony salts—have still the disadvantages that they are fairly toxic and cannot be injected except through the vein, and that if they are used intramuscularly they produce bad after effects. Messrs. The Union Drug Co., Calcutta, in placing this drug at our disposal, claimed that it was practically non-toxic and could be safely used intramuscularly and even subcutaneously. The toxicity of this drug was found to be about 400 milligrammes per kilogramme weight of body, as compared with 225 milligrammes per kilogramme of urea stibamine and aminostiburea.

The compound is described by the manufacturers as the sodium salt of urea stibamine. It is prepared by dissolving urea stibamine in caustic soda solution, carefully neutralizing the excess caustic with acid, then saturating the solution with carbon dioxide, filtering, and finally precipitating with sodium chloride. The sodium salt is collected and dried on a porous plate in a vacuum over sulphuric acid. The compound is supplied in sealed ampoules labelled 'novostiburea'. The preparation is in the form of light yellow powder forming a clear yellowish solution. It can stand boiling. The manufacturers claim that even tap water may be used for making the solution and advise that in such cases the solution should be boiled before

(Continued from previous column)

A subsidiary series was taken, of five children, between 3 and 7 years, who had recently recovered from an attack. Four of these showed no reaction in either arm, i.e., were 'Schick-negative' to whooping-cough. The fifth, who had been a very mild case indeed, showed a mild reaction to the antigen only. Thus recent cases can be said to give 100 per cent consistent 'Schick' results.

This investigation, however, goes to prove that a skin reaction for whooping-cough is never likely to enter the sphere of practical politics.

We are indebted to the courtesy of the Principal of the School for permission to publish these notes, and to the children who volunteered for the skin tests.

TABLE

Serial number	Religion and sex	Ages	Duration of illness in months	Weight in pounds on admission	Number of injections prior to cessation of fever	Total number of injections given	Total quantity of the compounds injected in grammes	Frequency of administration	Gain or loss of weight on discharge	SIZE OF SPLEEN BELOW COSTAL MARGIN IN INCHES		LEUCOCYTE COUNT PER C.M.M.		REMARKS
										Before treatment	After treatment	Before treatment	After treatment

T.W. = Tri-weekly.
D. = Daily.

use. For our use we prepared the solution either in tap water or distilled water, boiled in each case before use; this boiling rather improved the solution.

The conclusions, which we have arrived at, are the result of a study of 27 cases treated with this drug in the Public Health Department Kala-azar Centre. These patients were diagnosed as kala-azar by putting them under the following tests. On the first day of admission blood was taken for the total leucocyte count, differential count, search for malaria parasites, aldehyde test and Chopra's stiburea test. The patient was at the same time put under quinine in adequate doses for 3 days. If on the next attendance it was found that quinine had had no effect on the fever and all other tests indicated kala-azar, the patient was diagnosed as a case of kala-azar and the treatment commenced with novostiburea. Many of the patients come from distant villages sometimes 10 miles from Bandel and therefore had a tendency to become irregular in attendance as well as to stop treatment earlier than was desirable. This is the experience of all such kala-azar treatment centres existing in Bengal. As soon as the fever stops the patients, who are mostly poor cultivators, think that they have been cured and refrain from coming to the centre.

Out of the 27 cases, 20 were treated by the intravenous route and 7 were given intramuscular injections. Of the 20 cases treated by the intravenous route, 9 were given injections twice weekly, 7 injections thrice weekly and 4 injections daily, and of the 7 treated intramuscularly 3 were given twice weekly, one thrice weekly and 3 daily injections.

The table gives details of the results of treatment in all those cases in which the full course was completed.

From our experience the following conclusions have been arrived at:—

1. The compound can be safely given both by the intravenous and intramuscular routes.

2. The tissue does not become painful after intramuscular injection. Complaint of unusual uneasiness was not received even from cases coming from a distance of 10 or 12 miles.

3. The toxicity of the drug is so low that it can be given daily without any untoward symptoms.

4. There is a possibility of a daily injection of this drug effecting a much earlier cure.

5. In the 19 patients to whom the drug was given intravenously and was effective in stopping fever, the average number of injections required before the cessation of the fever was 3.6; in 4 it took two and in 10 only three injections. Whereas in the 7 cases by the

intramuscular route this average was 4.5 and the earliest cessation of fever was reported after three injections; this occurred in 3 patients.

6. In the 15 cases who had completed the course of treatment before they were discharged as cured, the average number of injections required was 9.

7. In the 4 adult cases who completed treatment the quantity of this compound required was an average of 2.35 grammes.

8. Marked gain in weight was noticed during the course of the treatment.

9. Marked improvement in the blood picture was also noticed.

10. In at least 4 cases at the end of the course of the treatment the aldehyde and Chopra's stiburea test had become negative; two of these had been given daily injections.

We wish to express our thanks to the Director of Public Health, Bengal, for kindly permitting the junior writer of this paper to work in the Bandel kala-azar centre to make these observations on the action of this drug on kala-azar patients and to Messrs. The Union Drug Co., Ltd., of Calcutta, for their generous supply of the drug with which the cases have been successfully treated.

(Note.—Novostiburea was used at the Calcutta School of Tropical Medicine as long ago as 1925 and the following reference to it will be found in the report of the School for that year. 'Only 4 cases in which Novostiburea was used can be included in this report.....; these were apparently cured with 10 injections given over a period of about 23 days'. Our experience in the following year was less satisfactory, as in the 20 cases in which this drug was used there were a number of relapses, but in the annual report for 1926 we commented on the low toxicity of the drug. Although the stability and the very low relative toxicity of this compound were strong recommendations, we did not feel that these compensated for its slower action and the lower degree of efficacy—compared with certain other antimonials which we were using at that time—that our first clinical trials indicated, and for this reason we did not extend our experience with Novostiburea.

However, this drug has enjoyed a certain degree of popularity on account of the special advantages we mention above, which it undoubtedly possesses, and we are pleased that it has been given a further clinical trial on scientific lines. Drs. Sur and Neogi's paper suggests that its degree of efficacy is very little, if any, less than that of urea stibamine and other antimonials now commonly in use, but, of course, they did not follow up their cases to see whether relapses occurred.—Editor, *I. M. G.*)

A Mirror of Hospital Practice

A CASE OF SPONTANEOUS PNEUMOTHORAX

By HUGH W. ACTON, C.I.E.

LIEUTENANT-COLONEL, I.M.S.

Professor of Pathology and Bacteriology and Director
and

DHARMENDRA, M.B., B.S.

Assistant Research Worker

Calcutta School of Tropical Medicine

SPONTANEOUS pneumothorax apart from the type associated with active tuberculosis is generally believed to be very rare; this is not so, however, because many cases are missed. Weber (1919) found about two hundred cases of spontaneous pneumothorax in apparently normal persons reported up to 1919; after that date there have been frequent references to such cases in the literature, very recently Palmer and Taft (1931) have described six cases, and Kjaergaard (1932) gives full clinical histories of fifty-one cases. In our study of about one hundred and fifty asthma cases we have come across one case of spontaneous pneumothorax simulating very closely a case of asthma. This case is reported with a short note on the aetiology of the condition with a view to bringing out the importance of this lesion.

Spontaneous pneumothorax is a term used for every case of pneumothorax which is not artificial or traumatic, i.e., where the presence of air in the pleural cavity is from any internal cause. Some authors consider as spontaneous only those cases in which there is no associated pathologic change in the lung, i.e., idiopathic spontaneous pneumothorax. Amongst cases of spontaneous pneumothorax in which there is an associated pathological change in the lung, 80 to 90 per cent are in tuberculous patients and are due to a tuberculous process, usually a cavity or caseation of a tuberculous gland and contiguous lung tissue. It is usually accompanied by a fluid pleural effusion and the prognosis is very grave; the patient generally does not recover, but there are rare examples of rapid recovery from pneumothorax unaccompanied by pleural effusion. Cases of spontaneous pneumothorax have been described in broncho-pneumonia and influenzal pneumonia. The idiopathic spontaneous pneumothorax, as the name implies, occurs in apparently healthy people and as a rule is not accompanied by any pleural effusion although some cases with effusion have been described. The prognosis in this type is very hopeful, they improve very rapidly and the average period of recovery is about five to ten weeks; no special treatment is required.

The condition is due to rupture of scar tissue caused by adhesions between visceral and parietal pleura, or of an emphysematous bulla

on the margin of the lung. The scar may be due to a small old healed tuberculous focus or to some other previous inflammatory process. The emphysematous bulla may similarly be the result of a tuberculous scar or secondary to some other condition. Some authors are of the opinion that all cases of idiopathic pneumothorax are tuberculous in origin, the tuberculous infection not being accompanied by any physical signs or positive radiological evidence. A theory has also been advanced (Palmer and Taft, 1931) that there is a tuberculous focus present causing the rupture; the collapse of the lung following the rupture and the resulting rest allow it to heal entirely without leaving any scar. Other workers believe the cause of these idiopathic cases to be non-tuberculous always.

Weber (1919, 1921 and 1932) maintains that the cause is mostly the rupture of a minute superficial emphysematous bulla (just below the visceral pleura) adherent to the parietal pleura—resulting from a healed miliary tubercle. As a result of local tuberculous lesions—for instance, a subpleural tubercle—there might be a local scar fixing a point of the lung to the parietal pleura. Close to such a scar there may be an emphysema bleb and the rupture of such a bleb might be due to some sudden movement accompanied by some sudden respiratory effort. The only difference, according to him, between the idiopathic spontaneous and the tuberculous spontaneous cases is that the idiopathic cases are connected with healed, non-virulent sterile lesions whereas the tuberculous cases are connected with still more-or-less-virulent foci containing living bacilli. On the other hand most of the cases of idiopathic pneumothorax reported have been in previously healthy people with no demonstrable pathologic change in the lung and the subsequent history showed them to be in normal health. Recently Oliver and Taft (1931) have reported six cases, in five of which the subsequent history was followed. Kjaergaard (1932) re-examined forty-nine cases three or more years after the pneumothorax and in forty-eight he could find no clinical or radiological evidence of tuberculosis, in the remaining one the patient was quite well for three years after right spontaneous pneumothorax and then developed acute tuberculosis of the left lung. Kjaergaard emphasizes that the spontaneous pneumothorax occurring in otherwise healthy individuals is not a manifestation of pulmonary tuberculosis. He thinks that the condition is due to the rupture of a valve vesicle, of which he describes two types—namely scar tissue vesicle and emphysematous valve vesicle.

Description of the case.—A European male, aged thirty-three years, was admitted into the hospital suffering from dyspnoea and orthopnoea on 2nd May, 1932, to be investigated for asthma. The trouble was of three weeks' duration, the dyspnoea started suddenly one evening when he was resting after his day's work.

All of a sudden he felt a choking sensation in his chest, the acuteness of the condition lasted for a few hours only. Since that day until the time of admission he had been suffering from dyspnoea, orthopnoea and cough; difficulty in breathing was most marked from 8 A.M. (when he got up from bed) to about 11 A.M., and it came on in spasms, each spasm lasting for about fifteen minutes.

Family history.—There was no family history of asthma; urticaria, eczema, or other allergic condition.

Personal history.—He had never previously suffered

Treatment.—No treatment other than rest in bed for a short period was advised. The patient improved rapidly and has been free from symptoms from that time. A skiagram taken on 5th September, 1932, i.e., four months and two days later (see figure 2) showed that the right lung had expanded fully, the right pleura was thickened and there were numerous small calcareous areas scattered near the bronchioles; there was a very doubtful peri-hilar lesion. Numerous small calcareous masses were present on the left side but there was no evidence of consolidation.

Fig. 1.—Skiagram of the chest showing complete collapse of the right lung.

Fig. 2.—Skiagram taken four months later showing the right lung fully expanded.

from asthma, urticaria, or eczema. Six years ago he suffered from pleurisy and since then had been suffering from bronchitis.

Physical examination of the chest.—The right base was dull, and on the right side, breath sounds were very feeble and the coin sound was present. There was slight myotatic irritability. The apex beat was in its normal position.

A skiagram taken on 3rd May, 1932, showed complete collapse of the right lung (see figure 1).

Blood count.—

Total leucocytes ..	9,000
Total eosinophiles ..	270 (3 per cent).
Hyalines ..	5 per cent.
Mononuclears ..	20 "
Polymorphonuclears ..	72 "
Arneth's count	I II III IV V
	19 40 35 4 2

Sputum.—Numerous pus cells, no eosinophiles. No acid-fast bacilli. Pneumococci and *Micrococcus catarrhalis* present.

Stools.—Trichuris ova. No *Entamoeba histolytica* and no pathogenic bacteria.

Urine.—Specific gravity 1016. Reaction acid. No albumin or sugar. Ether test for proteoses—positive.

Dermal tests.—Negative to hairs, feathers and various foods.

Von Pirquet test.—Positive.

Basal metabolism rate was ascertained to find out how far the left lung had taken up the function of the collapsed lung; oxygen consumption was 26 per cent below normal.

Features of the case

- (1) The onset of the trouble was not associated with any exertion.
- (2) There was no pain at the time of onset.
- (3) The dyspnoea and the orthopnoea were not continuous, but came on in spasms thus simulating very closely a case of asthma.
- (4) The position of the heart was unchanged.
- (5) The recovery was rapid and no special treatment was required.
- (6) Considering the previous history of pleurisy, the positive von Pirquet test and x-ray picture taken after the lung had expanded the pneumothorax in this case is very likely to be due to the rupture of a superficial emphysematous bulla resulting from a healed tuberculous focus.

A CASE OF IMPACTED VESICAL CALCULUS

By W. H. CRICHTON
MAJON, I.M.S.

Agency Surgeon, Kurram
and

TEK CHAND WASSON, L.M.P. (Agra)
Civil Hospital, Parachinar

H. G., a Muslim, aged 40, was admitted to the Civil Hospital, Parachinar, on the afternoon of 14th December, 1932, complaining of retention of urine.

The history was that for some months previously he had had some frequency of micturition with pain at the point of the penis on conclusion of the act; that latterly there had been some involuntary dribbling of urine; and that twenty-four hours before admission sudden and complete retention of urine had supervened.

On palpation of the abdomen it was found that the bladder was full and distended to a level three inches below the umbilicus in the middle line.

On the presumption that such a sudden onset of retention of urine in a man of his age was due to urethral spasm or congestion, the patient was put under an anæsthetic (A.C.E. mixture) and an effort was made to affect relief by means of a soft rubber catheter. But it was found impossible to pass this into the bladder and a metal one was next tried. This however also failed and a definite hard and unyielding obstruction to its passage was made out high up in the posterior urethra.

In view of the history of frequency, and pain at the end of micturition and the obvious possibility of the retention being due to a stone, the attempt was not pressed any further. As a measure of temporary relief the bladder was aspirated suprapubically and the patient prepared for operation on the following morning.

A suprapubic cystotomy was performed through a median vertical incision. As soon as the aperture in the bladder was large enough to admit a finger a stone was found which was firmly fixed in the prostatic urethra completely blocking the entrance from the bladder. It required considerable force to dislodge it.

On delivery it was found to be a small uric acid stone roughly pear-shaped in outline, flattened antero-posteriorly and showing a definite constriction or neck broadening out to a head beyond.

Looking back on the symptoms displayed one could now explain the frequency of, and pain on, micturition, as being due to the calculus acting as a foreign body in the bladder; this was followed by incontinence which presumably was due to the stone interfering with the action of the sphincter, after its impaction; and, later still, the sudden retention which was probably determined by a local chill or congestion. There can be little doubt that had this acute complication not supervened the stone would have gone on growing, partly in the bladder and partly in the urethra, and would ultimately have developed into a true 'hour-glass' calculus.

The patient made an uninterrupted recovery and was discharged from the hospital on the seventh day after operation.

PROLAPSE OF LUNG FOLLOWING AN INJURY

By MOHAMMAD ISMAIL, L.S.M.F. (Pb.), L.T.M. (Cal.)
Sub-Assistant Surgeon, In-Charge, Dispensary, Hujra,
Montgomery District

ON 29th October, 1932, Bahawal, a Moham-madan male, aged 35 years, was brought to the dispensary with the following injuries:—

(1) An incised wound 5 inches by 1½ inches on the right side of the chest in the mammary region; the third, fourth, fifth and sixth ribs were severed and a large portion of the right lung was prolapsed through the wound.

(2) An incised wound 3 inches long just above the left wrist, both bones of the forearm were completely cut, the hand was only hanging by the skin and flexor tendons.

Besides the above injuries he had others as well. At the time of admission he was in a moribund condition with severe symptoms of shock, but he was conscious. The injuries had occurred about twelve hours previously and the parts were wrapped in dirty rags.

Treatment.—Under chloroform, the prolapsed lung was washed with normal saline and was replaced in the chest. The pleural cavity was cleared of blood clots. Bleeding points in the chest wall were secured and the wound was stitched in layers without any drainage. His left forearm wound was cleaned thoroughly with water and saline lotions, and dabbled with acriflavine lotion 1—1,500. The bones were approximated and the wound was stitched without drainage and the arm was fixed in an antero-posterior splint. All his remaining injuries were similarly treated and were stitched.

All the wounds united by first intention. On the seventh day all stitches were removed, the left side of the chest was strapped as some of the ribs were fractured.

During all this time he complained of pain in the left side of chest and was running a temperature; gradually he developed signs of effusion on this side. On 17th November his chest was explored and fluid was detected. On 23rd November one pint of blood-stained fluid was removed from the left side of his chest, the first portion of the fluid containing some pus. The immediate effect of this operation was good and he became comfortable. Signs of pleural effusion did not disappear and on 27th November another exploration of the chest was done and pus was detected in the pleural cavity.

As the patient felt easier he refused an open operation for his empyema and on account of the nature of the exudate a subsequent aspiration was not successful. On 2nd December he started expectorating pus, and in about ten days he was quite free of all signs of effusion and his temperature became normal.

Splints from the arm were removed after the usual time and he had a firm union.

Two months after admission he was discharged cured on 19th December, 1932, and since then he has been keeping in perfect health.

I am greatly obliged to Sardar Sahib Dr. Hira Singh, my Civil Surgeon, for permission to publish this case and for his advice.

AMMONIUM CHLORIDE IN THE TREATMENT OF NEPHRITIC ŒDEMA

By S. K. ROY, M.B.

Chief Medical Officer, I. C. Hospital, Chanchal, Malda

A MAN, aged 26, suffering from ascites and marked generalized œdema of eight months' duration, came to hospital for treatment.

He was passing a greatly diminished quantity of urine which contained much albumen.

He was put on the following mixture three times a day:—

Ammonii chloridi	..	grs. 30.
Extracti glycyrrhizæ liquidi	..	min. 30.
Aquam menthæ piperitæ	..	ad ʒi.

Later, the dose of ammonium chloride was increased to grs. 40 and it was continued without any untoward symptoms.

In addition compound jalap powder—grs. 30 to grs. 60—was given bi-weekly according to the degree of constipation.

A salt-free diet of milk, rice and fish 4 ounces per day was given and the amount of fluid was restricted.

There was marked diuresis and in about four weeks' time complete disappearance of ascites and œdema except a little puffiness of the dorsum of both feet.

MAY

AIR TRAFFIC AND YELLOW FEVER

For every step we make along the road of progress payment in one form or another is exacted from us. Hitherto the cost of air transport has been slight in proportion to the gain, but unless we are on our guard and, from time to time, frame new international quarantine regulations to keep pace with the altered conditions, the loss that is possible to the world from the introduction of air-craft far outweighs the profit.

The speed of intercommunication between countries distant from one another has had the effect of bringing them near together. Formerly all the major infectious diseases were more or less limited to certain places because, with only a few exceptions, the time taken in ocean travel from endemic centres to other countries was greater than the maximum incubation periods of these diseases, so that any cases which might occur on board were discovered before the ship could reach the port of another country. But now, with journeys that used to take weeks reduced to a few days, it is possible for infected, though apparently healthy, persons to journey between almost any two countries in the world during the incubation period of any of the important infectious diseases. India as the principal home of plague and cholera is no doubt being carefully watched by the rest of the world, and we in turn have our eyes fixed on the endemic centres of yellow fever, which is our greatest menace.

The two centres of yellow fever in the world are Central America and the West Indies with the northern part of South America, and an extensive area of West Africa embracing all the British, French and possibly Belgian possessions there. At present the American focus is of no importance to India, but West Africa most certainly is. The mosquito vectors of yellow fever already exist in large numbers in East Africa, Egypt, India and the rest of southern Asia, all the islands of the East Indian archipelago and Australia. Therefore if once yellow fever breaks its bounds and reaches the western shores of the Indian ocean it will almost certainly continue its destructive course throughout tropical and subtropical Asia and the numerous islands to the south.

It has been argued that because this disease has never spread from the west to the east side of tropical Africa there is some unknown factor preventing this. What little evidence we have is quite against this theory for there is no evidence of racial immunity to infection

with yellow fever except such as is acquired by the races long resident or aboriginal in countries where it is endemic, and also it has been shown that mosquitoes taken from India to England act as efficient transmitters of the virus in the laboratory. The most probable explanation of the restriction of yellow fever to one side of the African continent for many centuries is that hitherto communication across central Africa has been infrequent and slow, and in the centre there is high land with a relatively cold dry climate which is probably unsuitable for the development of the virus in the mosquito. There has thus probably been a permanent break in the chain whereby infected persons and mosquitoes might have been expected to have gradually carried the disease from village to village from west to east. But now with air transport almost daily opening up new communications throughout Africa, it will not be long before it will be possible to cross the continent in two or three days at the outside and thus bring infected mosquitoes, as well as men in a stage capable of infecting mosquitoes but showing no signs of illness, to countries hitherto free from yellow fever. From Mombasa to India *via* Aden would only take three or four more days so that it may soon be possible for a man to reach India from West Africa in about a week. It is now authoritatively in some quarters stated that a person is infectious to mosquitoes for the whole incubation period which may be as much as ten days, as well as being infectious during the first three days of the attack. It is therefore clear that once air travel between West Africa and India becomes an accomplished fact it will be possible for an apparently healthy man who is infective to mosquitoes to reach India. The terrible implication of this is so clear that it needs no emphasis.

Should such a person reach India and infect some of the local mosquitoes the disease would almost certainly spread throughout the country with extreme rapidity and no sanitary or quarantine measures would be of any avail to check it. The reason for this strong expression of opinion is based on the analogy of dengue fever which shows similarities to yellow fever in many respects, as well as being transmitted by the same species of mosquito. We have numerous instances in the history of dengue of a sudden outbreak spreading throughout a wide area in a very short time and infecting almost all the population; the most recent example of this was the outbreak in Greece a few years ago. India is on the direct route to the rest of the East and should yellow fever reach here it would almost certainly spread to all the other countries where members of the genus *Aedes* are found, and which have been enumerated above. This makes it clear that in keeping yellow fever at bay we will be saving millions of people in other countries further east as well as in India itself.

It is true that H. R. Carter, than whom no one has had wider experience of yellow fever in America, is of the opinion that the spread of yellow fever is very limited as the infective mosquitoes are typical house dwellers and do not travel far from their original breeding places (the maximum he gives is 100 metres). We do not combat the accuracy of this observation, but no such limitation is observable in the spread of dengue fever during an epidemic, therefore we consider it justifiable to guard against yellow fever on the assumption that it will spread with a rapidity equal to that of dengue if it were to gain entrance to a country where such widespread explosive epidemics have been experienced on more than one occasion.

Another opinion held by some is that an attack of dengue will protect against a subsequent attack of yellow fever. Protection experiments with serum of persons recently recovered from dengue have so far failed to show any evidence of this.

The advisers on public health matters to the Government of India have long been wide awake to the dangers outlined above and in our correspondence columns in June 1929 the present Director-General of the Indian Medical Service, at that time Surgeon-General with the Government of Madras, published a letter in which he drew attention to the salient facts and counselled error on the side of safety regarding the prevention of the entry of yellow fever by aeroplane into India. We also have evidence that a year or so earlier than the publication of his letter this important matter had already attracted his attention.

Since that time he and his associates at headquarters have been untiring in their efforts to have world regulations of a east-iron nature framed to protect India from any possible chance of acquiring yellow fever. The aerial convention of the Office International d'Hygiene Publique adopted certain articles in which they placed the responsibility of guarding against the transmission of yellow fever by aeroplane from endemic centres on the country of origin, giving powers of veto of entry to the countries to which the aeroplanes might travel only on condition they provided an adequate explanation of such action. This was unsuccessfully combated by the Government of India through its public health advisers. But in May last year the efforts of the Director-General were slightly more successful, for as the result of an address delivered before the Yellow Fever Commission of the Office International d'Hygiene Publique after the articles of the convention had been decided upon, it was agreed that countries which considered themselves threatened with yellow fever should be the judges as to whether air traffic from infected or suspected countries should be prohibited.

On account of this we in India are looked upon as alarmists. This is made clear by the

following paragraph translated from the report of the Commission on Yellow Fever of the Office International, which is published in their monthly Bulletin of January last:

'It can be said that the chapter on yellow fever of the International Sanitary Convention for aerial navigation is a concession to the alarmist point of view. As it is the Yellow Fever Commission of the Office International d'Hygiene Publique which bears the responsibility of having enunciated the principles on which this code of rules is based, we have no hesitation in saying that except by totally forbidding aerial navigation we could not prescribe more rigid plans. The hygienists who for the last twenty years have borne the task of preventing the spread of yellow fever, which raged in Panama and other ports, have said that these proposals have exceeded the necessary limits'.

This may be so, but in these places yellow fever has already occurred and they are in close touch with countries in which the disease is endemic, so there is possibly a certain amount of acquired protection among the inhabitants which assists in keeping it at bay. Such conditions are entirely absent from India.

A great deal of work is now being done on yellow fever and important advances have been made recently. One of the most important of these from our point of view is the preparation of a fixed virus in the brain of a mouse which when inoculated along with the serum of a recovered yellow fever patient confers a considerable degree of immunity. If this immunity is eventually shown to be certain of production the compulsory vaccination of all travellers by aeroplane from an infected or suspected yellow-fever country to a yellow-fever-free country would greatly simplify the precautions at present necessary.

As a consequence of the importance of this matter to which the public health advisers of the Government of India have been largely instrumental in attracting the attention of other prominent sanitarians, a conference was held at the end of last year in South Africa. The Government of India was represented and no doubt their point of view was kept alive. Leading laboratory workers also attended so that the latest discoveries regarding protective vaccination and the mapping of yellow fever endemic centres by special animal experiments could be fully explained. The report of this conference is not yet received but it will no doubt be of great value and interest when it finally appears. But whatever the findings of the conference and whatever the weight of authority behind it, if it recommends the relaxation of the present regulations in any way, unless these recommendations are based on fully-proved facts and not on opinion, however experienced, we feel that the Government of India

will be justified in maintaining its present uncompromising attitude. Our reason for supporting this attitude of maintaining absolute certainty in the exclusion of yellow fever from India may be explained by a hypothetical example.

On the entirely imaginary assumption that India felt she must even go to war to keep out yellow fever, the cost of such a campaign would almost certainly be less than the cost of introduction of yellow fever to India and the countries further east.

Medical News

MEDICO-LEGAL AND CRIMINOLOGICAL REVIEW

If we may judge from the comparative neglect of the study of forensic medicine in England, as distinct from Scotland, the insatiable appetite of the public for information on the problem of crime is apparently not shared by medical men in their professional capacity. To meet the public taste popular articles on crime questions, modern methods of analysis, etc., are now a commonplace of the lay press. Scientific papers on these subjects by authoritative writers are, however, infrequent, and the medical enquirer must to a large extent confine his reading to textbooks. There are several reasons for this, but one of them is certainly the absence of a suitable medium of publication. We have just received the first number of the *Medico-Legal and Criminological Review*, a journal which incorporates the Transactions of the Medico-Legal Society. It has been something of a reproach to English forensic medicine that there has been no journal to set against the excellent publications to be found on the continent of Europe, more particularly in Italy, and we congratulate the Medico-Legal Society on having taken a distinct step forward in publishing their transactions in journal form; this should have the effect of arousing interest in medico-legal problems among medical men generally. The first step in impressing the conservative legal mind with the possibilities of new methods of analysis, e.g., the application of blood-grouping tests to the solution of questions of paternity, consists in the formation of an organized body of medical opinion, which will be stimulated by the publication of a journal under the aegis of the Medico-Legal Society. There has hitherto been an impression that forensic medical science is a matter for Crown experts and largely deals with the dead. A new branch of medico-legal work is now rapidly developing which deals exclusively with the living. We refer to the increasing importance of medical examinations both for injuries and for diseases resulting from modern industrial conditions, which form the basis of legal actions of many kinds. This form of medico-legal work touches general medical practice very closely. We congratulate the Society on having secured Messrs. Baillière, Tindall and Cox as their publishers and we wish the venture every success.

Congress of any paper submitted by a member who is unable to attend.

FIFTY YEARS AGO

(From the *Indian Medical Gazette*, May 1883)

I would now venture to make these cases (of malarial cachexia) a peg to hang some observations on, regarding an affinity, fancied or real, which on the surface seems to exist between acute rheumatism and the malarial fevers. They alike originate in chills and damp, insufficient food and clothing. Their symptoms closely approximate, save in the presence of inflammation of the joints in rheumatism, but in famine or relapsing fever, which I believe to be a hybrid malarial fever, this too may not be wanting. There are the same high temperatures, sometimes reaching 107° in the height of a quotidian paroxysm, in Assam, and the same profuse sweats, and urinary sediments. Their ultimate morbid changes are not dissimilar. The plastic effusions of rheumatism are akin to the albuminoid degenerations of the malarial cachexy. In the one case the blood retains its vitality in all its component parts, in the other its red blood corpuscles and albumen suffer serious damage, resulting in the visceral and glandular hypertrophies so well known in this dyscrasy. Therapeutically they are influenced by the same remedies, viz, quinine, salicine, and the salicylates.

One grave objection to this view is the comparative infrequency of rheumatic fever in India. In an experience extending over thirty years, I have met with only one case of rheumatic fever, and I imagine most medical men in this country could count their cases of this disease on their fingers' ends. What can be the reason of this comparative rarity? Can the two dyscrasias be the same, and does the one disease supplant the other under the modifying influences of climate and local conditions, producing paroxysmal fever in the feeble, ill-fed and ill-clad races of India with its extremes of temperature and moisture instead of developing into the more sthenic disease?

FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE, 9TH CONGRESS

THE Honorary General Secretary of the Far Eastern Association of Tropical Medicine announces that it has been decided that the 9th Congress which was to have been held at Nanking, China, from the 2nd to 8th October, 1933, will not be held this year. Notice of the dates and place of the next Congress will be intimated later.—EDITOR.

The Treatment of Conjunctivitis

By W. C. MACFETRIDGE, M.D.

(Abstracted from the *Medical Press*, 21st December, 1932, p. 509)

IN considering the treatment of conjunctivitis, it is first of all essential to bear in mind that the great majority of cases are due to bacterial infection. A few cases arise from other causes, such as smoke, irritant vapours, or errors of refraction, but the most common origin is microbic. As a rule it is not possible to say from a study of the clinical features of a case what the causal bacteria are, for a particular microbe does

not produce the same clinical appearances in every patient; and if we want to identify the micro-organism we must call in the aid of a bacteriologist. However, from the point of view of treatment it is generally not of great importance to be able to say what the exact microbe is. But patients must be warned against the danger of infecting others. They must be told that the discharge from the eyes is infective, and that towels, handkerchiefs, and other such articles are a common way of disseminating the disease. The conjunctiva is a membrane, and it forms in the orbit a mucous sac. When it becomes inflamed pus and muco-pus are secreted, and collect particularly in the folds and fornices of the conjunctiva. Our aim is to clear away all this purulent or muco-purulent discharge, and to destroy the invading microbes. It is a great mistake to put a bandage of any kind on a case of conjunctivitis. A bandage keeps the discharge in instead of helping to get it out; and by keeping the tissues bathed in pus it may easily produce serious damage to the cornea, which would be a very grave complication. It is not necessary to protect the eye from exposure to air. Fresh air is good for conjunctivitis, and patients should be encouraged to go out of doors. Let us now consider some of the principal means of treatment. Lavage of the conjunctiva is useful, and is essential in every case where there is much discharge. It washes out the pus and microbes and offensive material of all kinds, and cleans the conjunctival sac. The best way to carry out lavage is with a pear-shaped glass vessel called an *undine*, but if this is not available, it can be done very well with a glass funnel or the barrel of a large ear syringe, with a piece of rubber tubing attached. Whatever apparatus is used, it must be something that can be boiled *in toto*. Any bland lotion or weak antiseptic can be used, such as boric lotion, hydrarg. perchlor., 1 in 5,000, or Condy's fluid, 1 in 2,000, and the tepid lotion is directed in a gentle stream all over the eye and conjunctival sac, while the patient is instructed to rotate his eye in different directions so as to irrigate the various recesses as thoroughly as possible. This lavage is carried out two or three times a day, or, if there is much purulent discharge, as often as every hour.

Drops, or collyria, are an essential part of treatment. The most useful are zinc sulphate, argyrol, protargol, and silver nitrate. They are made up in watery solutions, and are best prescribed in half-ounce quantities. One drop of the solution is dropped into the eye three times a day, or oftener, with a glass dropper that must never touch the eye, and must be rinsed in boiling water before and after use. It is a good plan to put in the drops at meal time, as this regularizes the treatment. A drop should never be put in at bedtime, for the resultant reaction may interfere with sleep, and increased secretion may be pent up inside the closed lids. If one kind of drop does not seem to suit a case we should not hesitate to try another. Some drops lose their efficacy after a time; the conjunctiva seems to have got accustomed to them; while other drops, such as argyrol, produce an irritation if used too long.

Zinc Sulphate is one of the most useful of all eye-drops. It has the great merit of being clean and cheap, and is a specific in one kind of conjunctivitis—the angular variety. But it is rather pungent, and nervous patients complain that it is painful, and will not use it for this reason. The usual strength is two grains to one ounce distilled water, but we may begin with a weaker solution, and, if this is tolerated, work up to stronger solutions, as much as 1 per cent. A little boric acid is generally added.

Argyrol is a mild antiseptic collyrium, astringent, and not painful. Usually it is prescribed in from 10 to 30 per cent. solution, 25 per cent. being a good working strength. Like the other silver salts, it is supposed to have great penetrative power, but some authorities say that as a germicide it is negligible. Clinically it is beyond all doubt beneficial in many kinds of conjunctivitis, and as it is rather soothing, it often becomes a

favourite drop with patients. But it is messy, gives to linen a temporary brown staining, and if used over a long period may produce argyria. No patient should be allowed to use it unless under frequent observation. A patient of mine for whom I had prescribed the usual 25 per cent. argyrol drops disappeared for three months, and used the drops diligently in the interval; he then returned with an intractable brown staining of his conjunctiva, and said his appearance was spoiled.

Protargol is usually prescribed 2 to 5 per cent. Its uses are very similar to argyrol. It is of a light-brown colour, and is less likely to produce argyria, but it may give pain. On the whole, it is not so generally applicable and useful as argyrol.

Silver Nitrate is the most active and powerful germicide we have. It is greatly used in 2 per cent. solution, to be applied to the conjunctiva of the everted lids in gonococcal cases, in trachoma, and in other severe forms of conjunctivitis. Sometimes it is prescribed as drops in $\frac{1}{2}$ per cent. solution, but these should rarely be entrusted to patients as there is always danger of argyria.

Tannic Acid, grains 5 to the ounce, is useful, and a mild astringent collyrium.

We will now consider briefly some of the most common kinds of conjunctivitis:

Gonorrhoeal Ophthalmia.—In infants this is called ophthalmia neonatorum, and is a common cause of blindness. It is a most serious condition, alike in infant and adult, and the gravest view of the case must be taken from the start. It is not uncommon, if the gravity of the disease is not appreciated, to see both eyes lost within a few weeks. The most expert knowledge and treatment are necessary. As soon as the case is seen, active and vigorous treatment must be put in hand. Lavage with weak Condy's fluid, 1 in 4,000, every hour, or at any rate every two hours, is indicated. All pus must be cleaned away, and the eyes kept as clean as possible. Silver nitrate in 2 per cent. solution must be applied every morning to the everted lids, and $\frac{1}{2}$ per cent. drops instilled three times a day. The great danger is infection of the cornea, followed by ulceration and possible destruction of the eye.

Trachoma.—This is a very serious and very chronic form of conjunctivitis. Even in the most experienced hands, and with every opportunity for treatment, the average duration of a case is from four to five years. In patients who do not attend regularly the disease is practically incurable. The main treatment consists in the application to the everted lids of 2 per cent. silver nitrate in the early stages, and of copper sulphate stick in the later stages. This is done three times a week. The many complications that may arise, e.g., pannus, corneal ulcer, trichiasis, require special treatment. Patients should be warned as to the infectiousness of the disease.

Phlyctenular Conjunctivitis.—This is a disease of childhood and youth, and is the most common eye disease of children. It is thought to take its origin in the strumous diathesis, and undoubtedly is usually found in debilitated children. Treatment consists in application to the eye of unguentum hydrargyri oxid. flavi, 1 per cent., or of calomel powder once or twice a day; usually once is sufficient. The calomel is less irritating than the ointment, and may suit better in the early stages of the disease. If the cornea is involved, atropine must be added to the treatment. The general condition of the patient is very important. Fresh air and suitable food must be ordered. Cod-liver oil is very useful, varied perhaps with syrupus ferri iodidi. The disease is very liable to relapses, and treatment should be continued for some time after apparent recovery.

Angular Conjunctivitis.—This type of conjunctivitis is frequently met both in the acute and the chronic form. It is particularly common in a mild chronic form, with a little white discharge at the angles of the eyes. The specific treatment is zinc sulphate drops, from $\frac{1}{2}$ to 1 per cent. three times a day. If this is

carried out, cure is practically certain. The silver salts are of little use in this condition.

Acute Catarrhal Conjunctivitis.—This, a mucopurulent form of conjunctivitis, is of varying severity, and is often due to the pneumococcus. Treatment consists in the employment of the silver preparations, such as argyrol, 25 per cent., three times a day during the acute stages, and when the inflammation is subsiding we may change to the astringent drops, preferably to zinc sulphate. If in this form of conjunctivitis, or in any other form, the lids are stuck together at night by discharge, it is well to order a simple ointment to be smeared on the edges of the lids at bedtime. Boric ointment does very well for this purpose; unguentum hydrargyri oxidi flavi is too irritating, but a very useful and agreeable ointment is hydrargyri perchloridum, one part to three thousand parts white vaseline.

The Treatment of Diabetes in Children

By LOUIS R. GROTE

(From the *Prescriber*, Vol. XXVI, December, 1932, p. 349)

It is important that the practitioner should be familiar with the problem of child diabetes, as this disease is undoubtedly on the increase. The life-lengthening effect of insulin necessarily leads to an augmentation of the number of patients, and this naturally holds good with the younger generation. While in the pre-insulin era a diabetic child rarely lived longer than two years, experienced specialists now know a considerable number of young folk whose diabetes has had an existence of eight or ten years. I have a great many observations in which the diabetes has existed for more than eight years under constant protection of insulin, and in which a dangerous return of the disease is not to be expected. Without official registration an exact numerical statement is impossible, but approximate calculations induce me to believe that of every hundred diabetic persons from five to seven show the beginning of the disease before the sixteenth year. No fundamental difference exists between the disturbance of metabolism in childhood and that in adult life, but the symptoms of the former are in so many ways characteristic that a minute knowledge of details is necessary to carry out successful treatment. In earlier years child diabetes was usually regarded as a severe case, which was justified in consideration of the hopeless prognosis. In accordance with this fact, to-day we can state that about 90 per cent. of all diabetic children need insulin and usually continue to need it. But it is necessary to add that I cannot believe altogether in the dogmatic certainty of this somewhat dismal prognosis of the future. Observation of children, who have been diabetic for five years or longer, leads me to believe that with them also an increase of tolerance is possible and that the development into a diabetes absolutus (that is, a constant, unrepairable disturbance of the pancreatic activity) is by no means inevitable. In about ten years we shall be able to judge these questions better than to-day.

The exact observation of each single case shows greater variety within the range of the general need of insulin. It is very natural to regard the quantity of insulin required as a measure of the seriousness of the case, but by this schematic method we cannot accurately judge the different situation of the individual patient. The amount of insulin required is a factor to be determined mainly by the quantity of carbohydrates to be assimilated, and by the mass of cells of the body to be supplied. In the absence of an exact method for the determination of the insulin produced by the organism itself, the exact quantity of the insulin of a normal person is as yet not available. It is most probable that this production is mainly dependent on the two factors equally. I have suggested that the degree of serious-

ness of a case of diabetes may be measured by forming a product of the quotients—quantity of insulin (units): body-weight (kg.), and quantity of insulin: carbohydrates of the food (gm.), which as compensatory index approximately indicates the degree of the sickness. For simplification we multiply the result by 100. This index is reckoned on absolute aglycosuria and an optimal food supply corresponding with the state of growth of the child. I have watched this index during the last few years in many children, and I have found that in a surprisingly high percentage it improved. When the index lowers to 0, the child lives without insulin. Experience shows that an index above 100 corresponds to a relatively dangerous phase of the disease, in which dropping of insulin even for a very short time must lead to heavy acidosis or coma. It was noted, however, that children whose index in a certain state was far above 100 nevertheless were able to improve their tolerance by consequent use of insulin, and they again reach a phase of their metabolic disturbance far less dangerous than before.

The difficulties of the treatment of the child lie mainly in the greater lability of the blood-sugar regulation as compared with the adult. While in the adult a certain dose of insulin causes a gradual descent of the blood-sugar during the next three or four hours, which, if the dose is not extreme, does not overstep an amplitude of 100 mg. per cent., the same dose with a child under equal outward conditions (food) brings the blood-sugar down from 350 to 100 or even 50 mg. per cent. within a far shorter period. Therefore hypoglycæmic shocks are far more frequent in children than in adults. They develop faster and lead to stronger nervous indispositions, unconsciousness, cramps, and paralysations. But as hyperglycæmia can follow this state within a very short time, we often find in our practice that the physician cannot explain this paradox of a combination of great quantities of sugar in the urine and nearly simultaneous clinical hypoglycæmia as the result of incompatibility with insulin or resistance on the part of the child. It is important to point out this frequent mistake. Real resistance against insulin is very rare, and in childhood I have not seen it during my long experience. The combination mentioned leads to the fundamentally important fact in the treatment with insulin of a child, namely the necessity not only to define the injection in quantity, but also to adapt it in time to the curve of blood-sugar. Most children reach the highest point of their blood-sugar in the early morning hours between 5 and 7 o'clock. A second rise between 4 and 6 in the afternoon corresponds to this height. But there are many exceptions. The task of the clinical observer is firstly to control the blood-sugar every hour or second hour. The distribution has then to be done in such a way that the insulin is given on the ascending curve. This way alone prevents hypoglycæmia. Such outbreaks can discredit the whole insulin therapy.

The factors ruling the movement of the blood-sugar are manifold. From outside influence the food supply is of main importance; after that muscular activity. It is granted that the effect of the insulin is strengthened by an increased muscular activity. Therefore we often find that a child playing about, or engaging in football or some other kind of sport during the time of the strongest blood-sugar descent turns hypoglycæmic. On the other hand it is important to know that, as I already proved fourteen years ago, for a seriously diabetic person without insulin muscular exercise brings a rise of blood-sugar. In the child psychic factors play a greater rôle than in the adult, but I do not think that psychic influences cause the disease or even aggravate it in the long run. To the sudden change of moods of the child, to the faster reaction to joy or fright, this reaction of the blood-sugar corresponds exactly. I have often observed that such an influence causes a considerable glycosuria for one night or even a few hours of the day, which disappears the next day without changing the quantity of insulin.

However, contrary to usual surgical advice, chronic cholecystitis may, in approximately one-third of the patients, be successfully treated along medical lines. The risk of developing a surgical emergency or calamity while under medical treatment, is not greater than is the risk in the best elective gall-bladder surgery. Patients who have allowed their gall-bladder symptoms to go on for a number of years until their gastric acids have become low or absent, with definite and permanent pathologic process of the liver and biliary ducts, cannot expect as complete relief from cholecystectomy as if they had accepted immediate operation. Hence we believe emphatically that when medical management fails to relieve promptly then operation should be urged on the patient. We wish to emphasize the fact that patients with acute cholecystitis, empyema, jaundice or carcinoma have not been included in this study.

Remarks on Tuberculin in Diagnosis

By S. LYLE CUMMINS, C.B., C.M.G., M.D.

(Abstracted from the *British Medical Journal*, 7th December, 1932, p. 1089)

By the use of the original von Pirquet technique it was found that non-tuberculous persons proved to be quite as sensitive to tuberculin as the known cases. The conclusion drawn was as follows:—

The practical point at issue in diagnosis is the presence or absence of active disease. Surface vaccination is quite unreliable as a means of answering this question.

Later, with the introduction of the Mantoux intradermal technique, I decided to try out this method as one perhaps better calculated to differentiate between stages of tuberculous infection, and in 1928 and 1929 I applied the intradermal method both in healthy adults and in known cases of tuberculosis, comparing the results both as to end-point of tuberculin dilution causing reaction and actual size of reaction area. In these tests, the interesting fact came to light that the reactions tended to be, on the whole, more definite and the sensitivity more marked in non-tuberculous adults than in the tuberculous. A further comparison was made during 1929 and 1930, and the intradermal reactions to serial dilutions of tuberculin were studied on standard lines in 100 cases of pulmonary tuberculosis and in 100 non-tuberculous persons under treatment in the Cardiff Mental Hospital.

All these investigations tended to the same conclusion, which has been amply confirmed by numerous workers, that, as a test for 'active clinical tuberculous disease', the cutaneous and intradermal tuberculin tests are too delicate; and that 'positive' reactions elicited by these methods in adults cannot be interpreted to mean 'active' tuberculous disease. While this is true, however, the problem of the value of these cutaneous techniques in diagnosis is not quite so simple as it appeared to be when I attempted to exploit tuberculin in the diagnosis of tuberculosis in soldiers in 1909.

POSITIVE REACTION IN EARLY LIFE

It has been proved by many reliable workers that the cutaneous tuberculin sensitivity so constantly observed in healthy adults in 'civilized' and 'industrialized' communities is, as a rule, absent in infants, and that, while it tends to increase with each year of life, it is still very low in the earlier age groups except in the homes of 'open' cases of tuberculosis, where the contacts tend to give a high percentage of positive reactions even in infants and young children. This observation raises the question of the value of a 'positive' in early life, and here the answer is not so simple as in relation to adults. My own view, based, however, on an integration of the observations of others, is that a markedly positive reaction either to the von Pirquet or the Mantoux tuberculin test has a serious significance during the first year of life. There can, I think, be no doubt that sensitivity to tuberculin proves the existence of tuberculous infection; and, while we have reason to

know that infection is, in adults, not merely consistent with health, but usually present, we know also that very early infection, acquired in any considerable concentration before the tissues have had time to accommodate themselves to their bacterial environment, is very likely to lead on to severe and often fatal disease.

A recent paper by Blacklock (1932) indicates the extremely high risk of fatal tuberculosis in the case of infants heavily enough infected to harbour tuberculous lesions visible to the pathologist; and the Registrar-General's statistics show, year after year, that the death rate from this disease is exceedingly high during the earlier life periods. We should, therefore, view with grave anxiety the very early appearance of a 'positive' tuberculin response in an infant or in a child in the first year or two of life, since a 'positive' implies infection, and infection at this stage usually, though not always, implies the near approach of active disease.

A POSITIVE IN ADULTS

I have expressed the opinion several times already that a 'positive' in an adult brought up in an 'industrialized' or 'civilized' community has little or no diagnostic significance. This view, however, does not extend to 'positive' tuberculin responses in adults whose early years have been passed in communities of a 'primitive' type and, perhaps we ought to add, 'whose more recent ancestors have resided in communities with a primitive type of culture'. These adults, comparable perhaps in some respects to the earlier age groups in Europe and America, appear to develop tuberculo-allergy of a much more active variety than is common in adults in communities of an older civilization. Coming from districts which, through the industrial developments of recent years, have lately become endemic centres of tuberculous infection, African natives may possess an allergy potential far higher than what we encounter in this country, yet they are without the relatively high power of tuberculo-resistance common in adult Europeans. In such natives, a well-marked 'positive' tuberculin reaction has a much more formidable significance than elsewhere.

In Report No. XXX (vol. v) of the South African Institute for Medical Research (1932) will be found an account of tuberculin tests on South African native mine recruits on arrival for work at Johannesburg, together with the results of a 'follow-up' of the tested groups through their subsequent periods of work in the gold mines. On page 97 of the Report the results of this inquiry are set forth, and show that the incidence of tuberculosis was about five times as high among those who had given a 'positive plus' reaction than in those found negative to the dilutions used, 1 in 5,000 and over; while the mildly positive reactors were intermediate. The actual figures of incidence, based on 93,000 natives tested with tuberculin by the intradermal method, were as follows: in those recorded as 'positive plus', 1,547 per 100,000; in those recorded as merely 'positive', 633 per 100,000; and in the 'negative', 347 per 100,000. These figures can only mean that the 'positive plus' reactions were associated with active, though clinically unrecognizable, tuberculous lesions which tended to become generalized during the stress of a new and exacting occupation. This does not mean that a 'positive plus' reaction was diagnostic, even in these highly susceptible persons, of clinically active tuberculosis. It merely means that, out of 3,879 persons giving these marked reactions, sixty developed clinically active tuberculosis during the following year or so of work on the mines. The remaining 3,819 got safely through their mine contracts without being recognized as tuberculous, in spite of the repeated weighings and examinations which are in operation to detect and remove recognizable cases.

Has a strongly positive reaction any similar significance in this country? I have already expressed the opinion that in infants and young children it has this same kind of significance; that it must be taken to mean the presence of an active focus which, in early childhood, is always accompanied by danger of

generalization. In European adults, however, my own observations, as far as they go, do not suggest any such relation. Out of 100 mental cases tested with graded dilutions of tuberculin in 1929 and 1930, eight have since developed tuberculosis. Of these, one had reacted up to a dilution of 1 in 100,000, two to 1 in 10,000, four to 1 in 1,000, and one had been negative even to 1 in 500, the strongest concentration used.

Here the incidence was definitely greater among those who had been proved to possess low or negative tuberculin sensitivity; but the figures are too small to be of much importance. A far larger number have since been tested elsewhere by one of my co-workers, and it is hoped that a follow-up of their tuberculosis incidence will throw further light on the point at issue.

VALUE OF A 'NEGATIVE' IN EXCLUDING TUBERCULOSIS

So much for the diagnostic value of a 'positive' reaction to a cutaneous tuberculin test. But there arises also the question of the diagnostic value of a 'negative' in excluding tuberculosis. Recent work has gone far to prove that the diagnostic value of a 'negative' may be very great, especially in childhood. In attaching any weight to the value of a 'negative' in excluding the presence of tuberculous infection, the negative must be made as conclusive as possible; it is quite insufficient to stop short at a von Pirquet test, even with full-strength tuberculin, or at a Mantoux test with 1 in 1,000 tuberculin. Many persons negative to these concentrations are, in reality, positive if tested intradermally with 1 in 100 or 1 in 10.

There is another aspect of 'negative' findings, however, which deserves notice, especially in regard to adults—namely, the loss of tuberculin sensitivity which goes with advanced tuberculosis. This is hardly likely to introduce practical difficulties in diagnosis, as the nature of the disease is usually beyond doubt at the advanced stages in which the test may become negative. But if the word 'diagnosis' be extended to include prognosis, then cutaneous and intracutaneous tests may be said to have some significance, though only in the terminal stages. It does not appear that tuberculin sensitivity is ever absolutely lost until the very end, but there is a gradual fading of sensitivity, affecting both the intensity of the reaction to strong concentrations and the end-point of reaction to graded dilutions, as the resistance of the patient wears out under the stress of progressive disease. This fading of tuberculin sensitivity should, I think, be definitely distinguished from the desensitization which may arise in the course of a successfully resisted infection or through tuberculin therapy; a desensitization which is, in my opinion, to be associated rather with the acquisition of immunity than with loss of resistance.

I recently tested by the Mantoux technique six patients who had been under treatment for considerable periods, all of whom had arrived at a toleration of large doses of bacillary emulsion given subcutaneously. In one, the Mantoux test was completely negative in every dilution down to 1 in 500, the strongest concentration used. Four were negative to 1 in 10,000 but weakly positive to 1 in 1,000, that is to say, less sensitive than is commonly the case in tuberculous persons of their type. One, however, although he had received a subcutaneous dose of 0.7 c.mm. of bacillary emulsion a week earlier without reaction, experienced a sharp constitutional as well as a marked local reaction to about 1.1 c.mm. of old tuberculin intracutaneously. Apart from this anomalous case which was apparently tested just at a moment of raised tuberculin sensitivity, treatment with tuberculin had definitely lowered the allergic potential of these patients, yet all of them were doing well and in no sense 'terminal' cases.

F. Allen, testing native mine workers at the Witbank Coal Mines in the Transvaal, has observed that 'old mine workers', tested for a second time after some years of work, tend to be definitely less tuberculin-sensitive than at their first tuberculin test on arrival. Here it would seem that the repeated exposure to reinfection incident to life in the mines and in the

compounds has had the effect, not of raising, but of lowering the allergic state, though such men appear to be, on the whole, more resistant than new arrivals. One lesson appears to stand out clearly from all this South African work, with which I have had the privilege of being closely associated—namely, that while a marked positive Mantoux reaction is by no means diagnostic of clinically recognizable tuberculosis, it is to be regarded as the sign of an active, though 'larval', lesion from which infection may, under unfavourable circumstances, generalize throughout the organism. Another lesson, of greater importance from the point of view of the pathogenesis of tuberculosis, is that marked tuberculo-allergy may exist without any corresponding acquisition of tuberculo-immunity. Immunity and allergy may be due to the same cause, infection, but they are not in any sense identical or even, necessarily, coexistent.

Cutaneous tuberculin tests, then, whether of the von Pirquet or the Mantoux type, or of the type of Stichreaktion of Epstein, are reliable tests for allergy, and, by implication, for infection; but they are not of much value as tests for clinically active tuberculosis in adults nor as tests for the existence of acquired immunity.

KOCH'S SUBCUTANEOUS TEST

There remains, however, the subcutaneous tuberculin test as originally devised by Robert Koch. This test is definitely inapplicable to persons with pyrexia, a fact which greatly limits its utility in differential diagnosis; nor is it safe as a test in persons likely to be harbouring lesions of the easily activated type. In such persons, focal and general reactions are things to avoid, and there is no justification for exposing them to the risks incidental to activation of their lesions for the sake of an added point in the search for a diagnosis. There is one type of case, however, in which the risks are minimal and the advantages to the patient sometimes sufficiently important to justify the subcutaneous test. I refer to the chronic, productive, inert, sputum-negative cases which often come to our notice as ex-soldiers seeking to establish a claim to continuance of pension. These chronic and resistant cases stand the subcutaneous test well as a rule, and the risk is not serious. Koch's opinion was that a positive reaction to a dose of 10 milligrams might be regarded as diagnostic while there was no chance of a positive reaction of the general or pyrexial kind in a healthy person until the limit of 25 milligrams was reached. These quantities are, perhaps, expressed too exactly, and, in the light of modern experience, most of us will hesitate to draw the line sharply between tuberculous infection of a degree consistent with health and tuberculous infection just severe enough to constitute disease. But, of all the tuberculin tests, the subcutaneous method of Koch remains the most valuable in diagnosis. It depends upon general and focal reactions which are, in themselves, evidence of active disease, and, when elicited by tuberculin, may be accepted as diagnostic of clinically active tuberculosis. The only thing against it is its risk, and, in my opinion, there is no excuse for taking any avoidable risk in the attempt to establish a diagnosis.

I have indicated one kind of case in which Koch's original test may be applied with safety, and there are doubtless fairly numerous cases in which the subcutaneous test may be used without ill results by experienced physicians. Apart from these, it appears to me that the Mantoux test, applied with due skill and interpreted with discretion, is calculated to give valuable information, whether positive or negative, in the earlier years of life, and that apart from the diagnosis of clinically active tuberculosis, this test is invaluable as a means for determining the distribution of infection in communities in which epidemiological investigations are contemplated. On the whole, for purposes of diagnosis in man, the tuberculin test, in all its varieties, is definitely inferior to the combined radiological, physical, and laboratory examinations which have come to be the routine methods.

Reviews

DISEASES OF THE HEART.—By Sir Thomas Lewis, C.B.E., F.R.S., M.D., D.Sc., LL.D., F.R.C.P. London: Macmillan and Co., Ltd., 1933. Pp. xx plus 297. Illustrated. Price, 12s. 6d.

In these days when the medical publishers of Great Britain and the United States provide us with an average of two or three new books or new editions a day, it is not very often that one is able to say 'This is the book I have been waiting for'; Sir Thomas Lewis's book on diseases of the heart provides us with this opportunity. It is a book that every student should read when he is 'clerking' in the medical wards. On the other hand it is a book from which the practising physician will get very great benefit. It gives a very clear statement of the present-day conception of heart disease. Those who first entered the medical wards of their hospital twenty years or so ago will remember how they plunged into systolic murmurs, presystolic murmurs, and valvular incompetences and stenoses, how when they could time a murmur and percuss out the cardiac dullness they felt that the diseased hearts of the world were at their feet, and how a year or so later they were alarmed by their younger colleagues' glibness in discussing electrocardiograms which they themselves were always afraid of holding upside down. This is all changed now, and even the electrocardiograph has been made to take its place; in this book it occupies a modest place, considering the important part the author has himself played in furthering the science of electrocardiography. The emphasis in cardiology has been transferred from anatomy to physiology, and the stethoscope does not play such an important rôle in the diagnosis and prognosis of heart disease as it did some years ago.

The following extract is taken from the preface: 'I have become more and more convinced of the need for simplicity; and it was apparent that little of the graphic work could profitably be taught to men entering practice, whose foremost interest must be in observations they themselves can make upon their patients..... I have tried to strip my subject of intricacies and redundancies, of unnecessary technical terms, named signs, and old trite phrases, for these begin to stifle Medicine'. One cannot say more in praise of the book than that the author has maintained these principles throughout. We will add that the book is surprisingly cheap for one of its size and quality.

APPENDICITIS: ITS ÆTIOLOGY AND PATHOLOGY.

—By L. Aschoff. Translated by G. C. Pether, M.D., M.R.C.P. London: Constable and Company, 1932. Pp. vii plus 153, with 36 illustrations. Price, 16s.

PROFESSOR ASCHOFF puts forward in this monograph his views on the pathology of appendicitis. He has approached the subject from the bacteriological and histological point of view, and he includes a critical review of previous bacteriological investigations. In conducting his own investigations, he has devised a technique of his own. The book should be read by all bacteriologists, whose work is concerned with appendicitis or examination of surgical specimens.

His investigations are mainly concerned with appendicitis as it appears in Germany, and therefore possibly differ from the conditions found in England. His last chapter in the clinical investigations is perhaps the most interesting to surgeons and general practitioners. His evidence is obtained from 1,000 cases, the majority of which were examined histologically by himself. The main interest lies in the fact that in these 1,000 cases, the clinical diagnosis has been checked with exact histological examinations on a uniform plane.

I do not think it will be suggested that German surgeons are less careful than their colleagues in the rest of the world, and it should therefore be matter for

very serious consideration to surgeons that only 75 per cent. of cases diagnosed as acute appendicitis presented pathological evidence of the disease. Professor Aschoff suggests the use of the term 'pseudo-appendicitis' to describe the other 25 per cent. To those who discouraged the use of the term he replies 'As soon as one knows what has actually happened in these patients, one will of course be able to use the correct term'.

His findings on chronic appendicitis are equally calculated to promote modesty in surgeons. Only 50 per cent. of the cases operated on for this condition showed signs of inflammation. Here we have ample justification for those who advocate a complete examination of the abdominal viscera through an adequate incision when a diagnosis of chronic appendicitis has been made. The very popular McBurney incision is entirely unjustifiable in the so-called chronic cases.

On the other hand, he justifies the routine removal of the appendix in the course of abdominal operations for other conditions, by finding evidence of disease in over 33 per cent. of cases where no clinical evidence was noted.

Finally, there is one extract every surgeon should bear in mind before lightly advising operation for appendicitis. 'One should not underestimate the pain which may be caused by the scars or adhesions which have followed operation'.

Professor Aschoff's monograph is mainly of interest to bacteriologists, but his last chapter on clinical applications constitutes a very serious indictment of modern surgery. It is all the more serious in that nothing is further from the author's intentions.

A. H. P.

A SHORT PRACTICE OF SURGERY. Vol. II.—

By Hamilton Bailey, F.R.C.S. (Eng.), and R. J. McNeill Love, M.S. (Lond.), F.R.C.S. (Eng.). London: H. K. Lewis and Co., Ltd., 1932. Pp. viii plus 475. With 349 illustrations of which 58 are coloured. Price, 20s.

THERE are so many excellent textbooks of surgery now available that a new one has to justify its appearance by presenting the subject in a new light or appealing to a class of reader not yet catered for. It is generally agreed that the standard textbooks have grown too big and that there is room for a smaller one, which will present the subject in a simplified form to enable junior students to lay a sound foundation of knowledge of principles and of the lie of the land before plunging into the forest of detail which the larger works, with an eye on the higher examinations, invite him to try to absorb. The present work certainly does not fill this gap, as it contains very little surgical anatomy or pathology, no morbid histology and the presentation of the subject lacks the systematic form so necessary for students. One must conclude that the authors are writing for practitioners, and as a brief clinical review the book is excellent. There are short snappy descriptions of symptomatology, with an abundance of those 'good tips' which readers of Mr. Bailey's other works will expect; the fat female of 40 suggests all sorts of things besides gallstones, depending on one's line of practice, but how many readers know why they should beware of the man with a glass eye and an enlarged liver? The common conditions affecting each region are dealt with first and then the rarer diseases in small type, a sound method had a better sense of proportion been shown in the allotment of space. Brief notes on such subjects as hepatoptosis, sarcoma of the stomach, aneurysm of the splenic artery, actinomycosis of the liver, mesenteric cysts, cystic pneumatosis of the small intestine, to mention only a few of the rare conditions referred to, are of doubtful value in a book which purports to be only a brief survey, and, when one finds that the symptoms of chronic cholecystitis are dealt with in seven lines and those of chronic duodenal ulcer in half a page, one feels that the space might have been more usefully employed for fuller descriptions of

common conditions. The sections on treatment are generally very brief, with no operative details, but this is not always so, the chapter on appendicitis is very full and the Ochsner-Sherren treatment, which is advised for cases of over 48 hours duration, is discussed in detail. There is a long and excellent account, one of the best we have seen, of the subphrenic abscesses; the operations for excision of the rectum and for exposure of the brain by an osteoplastic flap are described in considerable detail, but there is no description of the operation of gastro-enterostomy, though its complications are discussed. The chapter on thoracic surgery is a brief and thoroughly up-to-date survey of the subject and the diagnosis of hernia is well described and beautifully illustrated. At the end of the book are the chapters which usually come near the beginning, those on infections and tumours, and here we find no details of the courses of treatment for syphilis, mercury advised as the adjuvant drug and bismuth stated to be useful in patients who show intolerance to arsenic. Inequalities such as these are very serious blemishes in a book whose get-up and beautiful illustrations give it a very attractive appearance. The style is crisp and pleasant to read, but the price of the two volumes and the limitations pointed out will prevent it competing very seriously with the existing popular books.

W. L. H.

COLONIC IRRIGATION.—By W. Kerr Russell, M.D., B.S. Edinburgh: E. & S. Livingstone, 1932. Pp. ix plus 191. Illustrated. Obtainable from Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 7-14.

THE introduction calls attention to the casual way in which most people, including doctors, treat constipation.

Then follows a most interesting account of the origin and gradual development of clysters or enemas, from before 1500 B.C., through the middle ages to the present day.

One theory of the origin of enemas (quoting Pliny's account) is as follows:—It is said that a certain bird, similar to the stork, called the ibis, and peculiar to Egypt, showed man the secret of lavages, because when it wants to evacuate, it syringes the anus with its beak filled with water from the sea.

The clyster reached the height of its popularity during the early years of the reign of Louis XIV. Society women found that it was an effective method of improving the complexion, and the treatment became a fashionable craze in Paris, many persons having as many as three or four treatments a day. It is stated that Louis XIV often received ambassadors and courtiers while seated on his commode. He had over 2,000 injections during his lifetime. The giving of a clyster to Louis XV was however a court ceremony attended with suitable pomp and ceremony by all the members of the Faculty!

Large numbers of similarly interesting historical facts are given in the first part of the book.

Following this is the rather dry anatomy and physiology of the colon, and then the bacteriology.

Most of the well-known types of apparatus for colonic lavage are then minutely described and also their methods of use. This section could be condensed a lot, without loss of efficiency, as it is mainly an endless repetition in varying words of the same principle. The solutions in most common use and prescriptions for making them, followed by the dangers of the treatments are then given. The book ends up with the conditions benefited. Needless to say nearly every known disease is included. Appended is a useful bibliography and index.

One feels after reading this monograph that purgative and laxative drugs should be abolished forthwith, and that their place should be taken by a douching or irrigating apparatus in every bathroom, if one is to preserve one's health!

A very entertaining book in its opening chapters and full of useful information in the remainder. Well worth reading by everyone who orders enemas to be given—and which doctor does not?

J. F. C.

MASSAGE AND REMEDIAL EXERCISES IN MEDICAL AND SURGICAL CONDITIONS.—By N. M. Tidy. Bristol: John Wright and Sons, Ltd., 1932. Pp. xii plus 429. Illustrated. Price, 15s.

THE present-day surgeon and physician, but especially the surgeon, must have a working knowledge of the many aids to treatment available under the wide inclusive term of 'physical therapy', if he is to give his patients the full benefit of modern knowledge. Most medical schools give no training in the subject at all and the massage department is looked on by students, house-surgeons, and, one is ashamed to say, many older members of hospital staffs also, as a fit place to send all the old 'chronics'. That this is absolutely wrong cannot be denied, but one usually finds that the youngest department always has the 'junk' thrust upon it in the hope that the 'new-fangled' and only half-understood treatments will succeed where ordinary treatment has failed. And the surprising thing is that these old chronics are improved, mainly by the patience, perseverance, and common sense used in the physical therapy department.

This book, besides dealing with treatment by massage and remedial exercises alone, as the title suggests, gives a concise account of almost every known medical and surgical disease, as almost all can be benefited by exercise of some part of the body. The ætiology, pathology, and symptoms are all accurately and shortly described, and then follows treatment which is dealt with very fully. Instructions are also given as to the length of time it is usually advisable to persist with treatment in any particular case. As the author states in the preface her aim has been to provide most details where other books provided least. In this she has definitely succeeded. In fact many well-known medical and surgical textbooks might with advantage amplify their sections on treatment by passages from this book.

The book will be invaluable to all massage students, teachers, and practitioners, and could be read with advantage by all keen medical men who wish to gain new ideas in treatment which, in most textbooks, is dismissed in one word—massage.

The illustrations and general arrangement of the book are excellent.

J. F. C.

SURGICAL ERRORS AND SAFEGUARDS.—By Max Thorek, M.D. Philadelphia and London: J. B. Lippincott Co., 1932. Pp. 696, with 668 illustrations. Obtainable from Butterworth and Company (India), Ltd., Calcutta. Price, Rs. 33-12.

As the author points out in his preface, there is no shortage of surgical textbooks to tell us what to do and how to do it, but it is seldom that they tell us what not to do, how to avoid complications and technical errors, and how to act when face to face with some of the abnormal circumstances that so frequently present themselves during the course of an apparently routine surgical operation. Scattered descriptions of mishaps and accidents exist throughout the literature, but this is, so far as is known, only the second occasion on which an effort has been made to arrange them systematically in one volume.

As it is not often that unsuccessful cases are placed on record, the collection of the material for this book must have involved considerable and painstaking work. A regional arrangement has been adopted, sections dealing with anaesthesia, pre- and post-operative treatment, the treatment of the 'bad risk' case and a chapter on gynaecology being included. On the whole the subject has been treated in a practical and instructive manner, though here and there one notices that redundant matter has been included, making the book

rather unwieldy without adding to its usefulness. The illustrations are also rather more numerous than is justified by the text. If the work reaches a second edition, the author would be well advised to curtail its size.

The publishers are to be congratulated on the clearness of the type, reproduction of the illustrations and the general presentation of the book.

J. C. D.

COMMON SKIN DISEASES.—By A. C. Roxburgh, M.A., M.D., B.Ch. (Cantab.), F.R.C.P. (Lond.). London: H. K. Lewis and Co., Ltd., 1932. Pp. xxx plus 322, with 8 plates in colour and 110 illustrations in the text. Price, 18s.

This book is one of the volumes that have been published in the General Practice Series. The author is physician in charge of the Dermatological Department of St. Bartholomew's Hospital and has been able to present the wealth of his large experience in a simple and concise manner for the benefit of the student and practitioner.

At the beginning of the book Dr. Roxburgh gives an index of the lesions to help in the preliminary diagnosis of these diseases; this index although not, in the reviewer's opinion, strictly accurate will be of the greatest help to the student in his early study of dermatology. The skin diseases are divided into sections according to their causation—a very good method of classification. The illustrations, consisting of 8 coloured plates and 110 half-tone figures in the text, are very good.

As an introduction to the study of dermatology, this is the very best book that we have encountered for many years; we can strongly recommend it to the student or practitioner, and the price is moderate.

H. W. A.

AN INTRODUCTION TO DERMATOLOGY.—By R. L. Sutton and R. L. Sutton. St. Louis: The C. V. Mosby Company, 1932. Pp. xvi plus 565, with 183 illustrations. Price, \$5.00.

This book has been written by the well-known dermatologist, R. L. Sutton, in conjunction with his son, and is very well illustrated by 183 half-tone plates. Each disease is treated in a brief and concise manner—this will appeal to the student. The volume is really a digest of the elder Dr. R. L. Sutton's well-known textbook on diseases of the skin. The authors have succeeded in their object, and the book can be recommended to those who require a short and concise account of these skin diseases.

H. W. A.

DISEASES OF THE EYE.—By A. Rugg-Gunn, M.B. (Edn.), F.R.C.S. (Eng.). London: William Heinemann (Medical Books), Ltd., 1933. Pp. xli plus 188. Illustrated. Price, 12s. 6d.

In English-speaking countries there are so many textbooks for undergraduates of medicine to gain their knowledge of ophthalmology from that one is surprised at the appearance of yet one more. The book, however, is written primarily for the use of the general practitioner. It includes a description of all the more common types of eye disease with a simple, concise account of their pathology and with special attention to the principles of treatment that he is likely to come across in the course of his practice. In India, where so much eye disease abounds everywhere, this knowledge is all the more important, and if only the more serious forms of eye disease could be diagnosed early by the general practitioner, how much less the incidence of blindness would be. It is pathetic, but nevertheless true, that so many eyes have been lost by such diseases as glaucoma and corneal ulcers, and all from a lack of a simple knowledge of the principles of ophthalmic treatment.

The contents of this small book consist of twelve chapters arranged according to an anatomical classification with an appended materia medica of the majority

of drugs used in ophthalmology. In addition there are 8 plates and 21 figures in the text, all of which have been specially drawn for the book. It is unfortunate that a whole page should be devoted to the medical treatment of cataract which is of very little use and might well be omitted, as likely to mislead the general practitioner.

The work undoubtedly supplies a want. It is written in a clear, concise and simple style which can be easily understood by the general practitioner, who will find in it a wealth of practical information. We strongly recommend the book and, as its price is very moderate, it should find a place in the library of the medical man working in India.

E. O'G. K.

MEDICINE: ANALYTICAL REVIEWS OF GENERAL MEDICINE, NEUROLOGY AND PEDIATRICS. Volume XI, December, 1932, No. 4. Baltimore, U. S. A.: The Williams and Wilkins Company. Pp. from 371 to 535. (English Agents are: Baillière, Tindall and Cox, London.) Price, 21s. per volume and postage 2s. 6d. Single Copy 6s. 9d.

This journal has already made its mark as a first-rate journal dealing with general medicine, neurology and pediatrics, and the editorial board deserves congratulation for consistently keeping the standard at such a high level. The December number of volume XI is likely to be of special interest to clinicians and physiologists.

The first article deals with the adrenal cortical hormone. The function of the adrenal cortex is not definitely known at the present time, though various theories have been advanced. An attempt has been made to obtain an active preparation of the suprarenal cortical hormone and by means of it, to study adrenalectomized animals, subjected to various dosage over long periods. The hormone has also been given extensive trials in various types of cases, including Addison's disease, in the Mayo Clinic. Though no definite statement can be made with regard to the function of the suprarenal cortex, this piece of research would go a great way in advancing our knowledge about the physiology of the gland.

The second article presents in a masterly manner the salt and water metabolism in nephritis, a subject which has remained debatable to this day. The causation of oedema in nephritis has been frequently explained on the basis of salt retention alone, but the explanation is not as simple as is generally believed. The subject has been taken up from all angles of approach, and it will form very illuminating study to all those interested in experimental medicine and physiology. The bibliography at the end of this chapter is worth special mention.

R. N. C.

THE ORGANS OF INTERNAL SECRETION.—By Ivo Gekkie Cobb, M.D., M.R.C.S. Fourth Edition. London: Baillière, Tindall and Cox, 1933. Pp. xlii plus 303. Price, 10s. 6d.

The literature on endocrinology has grown enormously in recent years so that it is difficult for anyone not engaged in teaching or research work on these or allied subjects to obtain a comprehensive view of the facts upon which modern ideas are based. As the use of organic preparations is now an established method of treating disease and one which will undoubtedly form a large part of treatment in the future, the general practitioner has always been on the look-out for a treatise which will give him the essential features of the subject without going into too much academic detail. In the fourth edition of Dr. Cobb's book, he will get a book answering his requirements. It is a book of moderate size, full of up-to-date information on practical points. The physiological and pathological aspects of the different ductless glands have been briefly discussed and the rationale of their therapeutic application in diseases explained. A chapter on obesity

with special reference to its relation to the endocrines is given. In the chapter on the application of the hormones, a list of the various gland preparations available in the market is appended. This will be of great help to practitioners in prescribing the gland preparations.

R. N. C.

ACIDOSIS AND ALKALOSIS.—By Stanley Graham, M.D., F.R.F.P.S., and Noah Morris, M.D., B.Sc., D.P.H., F.R.F.P.S. Edinburgh: E. & S. Livingstone, 1933. Pp. xii plus 203. Illustrated. Obtainable from Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 5-10.

DURING recent years, the disturbance of the acid-base equilibrium in the body is being more and more widely recognized as an important factor in the causation of disease. Within the last 50 years, a good deal of research work has been done which has helped to throw light on this difficult physiological and chemical problem. It has, for instance, been generally accepted that for the organism to be maintained in a state compatible with life, the reaction of the inner fluids must be slightly alkaline and that much deviation from the physiological point of neutrality is disastrous. The factors contributing to the maintenance of this physiological state of neutrality in the system are very complicated indeed.

Owing to intensive work done within the recent years, evidence is accumulating which goes to show that a disordered metabolism arising out of or leading to a disturbance in the acid-base equilibrium is the cause of many morbid conditions and that many of the phenomena in disease are manifestations of the body's activity in preventing a change in the reactions of its fluids.

We welcome the laudable attempt of the authors to present a general survey of this very intricate subject in a comparatively simple and easy way. The subject is a highly scientific one bristling with complexities and technicalities. For its thorough understanding, not only a knowledge of higher mathematics and chemistry, but also of bio-chemistry and bio-physics, is necessary. The authors have avoided discussions on controversial problems and have put the general outline of the subject, specially in its relation to the causation of disease, in a clear, concise and cogent way, which, we hope, will be of great help to those who are making higher studies in clinical bio-chemistry.

J. P. B.

INFLUENZA: A CLINICAL LECTURE.—By T. B. Layton, D.S.O., M.S. (Lond.), F.R.C.S. (Eng.). London: Ash and Co., Ltd., 1933. Pp. 35. Price, 1s.

THIS little pamphlet, written by a well-known London throat specialist, should prove very useful to the busy practitioner during an influenza epidemic, and we can strongly recommend it as a book to be slipped into the pocket and read in one's car during the morning round. There are many features that appeal to the reviewer, but the writer's advice on the subject of alcohol in acute disease has made the most permanent impression; he warns us that it should be presented aesthetically, and he suggests that champagne out of a medicine glass is not the same as champagne out of a champagne glass. This is true to a certain extent, but it is mainly applicable where the patient has a taste for champagne and is used to drinking it out of the orthodox glass. Similarly, good advice on the subject of influenza is good advice in whatever form it is given, but some readers find it more palatable when the writer has taken a little extra trouble over its presentation.

The author says 'It (influenza) is probably a virus disease due to some ultra-microscopic living organism that can pass through a filter which will hold up anything large enough to be seen with such microscopes as have yet been invented', and he is probably right.

L. E. N.

FAVOURITE PRESCRIPTIONS.—By E. Ward, M.D. (Belfast). Third Edition. London: J. & A. Churchill, 1933. Pp. viii plus 148. Price, 7s. 6d.

THIS is one of these invaluable little books that contain all the information a prescriber can possibly want. The publication of the new pharmacopœia has stimulated writers and publishers of these prescription books to produce new editions, and we have received many for review. The present volume seems to be as complete, as concise and as suitably printed and bound as any we have seen. The changes in the new pharmacopœia, such as the new inclusions, the exclusions, and the changes in strength and dosage of various drugs, are indicated by stars and crosses, without addition to the bulk of the volume. There is a useful section on the treatment of poisons, and another on dietary; the latter provides the only criticism we can make. A dietary table for a disease like diabetes is of course very helpful, but can one prepare tables for conditions like anæmia and eczema, clinical manifestations with such manifold ætiologies? The greater part of the volume consists of useful prescriptions; these all appear to be very sound indeed. It is a book that deserves a wide sale.

THE RISE OF PREVENTIVE MEDICINE.—By Sir George Newman, K.C.B., M.D., F.R.C.P., Hon. D.C.L., LL.D. Oxford University Press, London: Humphrey Milford, 1932. Pp. 270. Price, 10s. 6d.

THE history of preventive medicine is essentially the history of medicine as a whole; the highest aims of physicians of all times have been prevention rather than cure. The tide, from century to century, has now flowed towards prevention and has then ebbed towards cure. Sir George Newman, himself one of the greatest living exponents of the practice of preventive medicine, has here given us as connected and concise a history of the birth and growth of the science of medicine as one could wish to read.

The reading of a history like this is very good for our sense of proportion; we are inclined to think that the advances that have been made in our own time are prodigious. From our point of view, the man who has been away from all practice for 20 years would find himself entirely out of date in many matters, but in a thousand years time, or even in a hundred, will the contrast between 1913 and 1933 be so very great? The early papyri show that practice in those days consisted of a mixture of magic and medicine; to-day many of our patients still believe that warts can be charmed away, and Harley Street is not entirely free from magic boxes. A thousand years before Christ the opinion was current in Egypt that 'every disease is occasioned by dietary'; we believe that this opinion is still maintained, and with good reason in Coonoor to-day. And so we progress.

The reviewer has always held the opinion that specialization in medical practice is of comparatively modern origin; he is pleased to see that this book confirms his opinion—provided a sufficiently wide interpretation is given to the word 'comparatively'. There does not seem to be any reference to specialization during the First Dynasty or even at the time of the Ebers papyrus, but in much more recent times Herodotus (500 B.C.) recorded that in Egypt they were more advanced than in other parts of the world and that there 'each physician treats a single disorder and no more'. He also found that to avoid 'gnats' the people lived in high towers, or used nets; so even they had their Ronald Rosses!

However, there have been many lapses since those times, and in England it took the Black Death and other similar expensive lessons to start us on the path of preventive medicine again. The book takes us up to the time of Sir John Simon; the next chapter might well be entitled 'From Sir John Simon to Sir George Newman', had it been written.

L. E. N.

MANUAL OF HYGIENE AND PUBLIC HEALTH.—By Ral Bahadur Jāhar Lal Das, D.P.H. Third Edition. Calcutta: Butterworth and Co. (India), Ltd., 1932. Pp. xxi plus 661. Illustrated. Price, Rs. 3-8.

THAT a third edition of this manual has been called for since 1925 is proof that it fulfils a definite demand. It presents in clear and simple language the salient facts of public health considered necessary by the author for medical students. It will be found useful for reference by public-health students, though it would naturally require to be supplemented by wider reading. One or two points we might suggest for the next edition. In a student's manual it is useful to give a scale of measurements so that an accurate idea of the dimensions of the objects illustrated is obtained, e.g., on p. 436, the adults and embryo of the ankylostoma are shown as approximately of the same size, and no indication of the natural size is given; and again the illustration on p. 437 of the hook-worm larvæ penetrating the skin, suggests something of the size of an earthworm entering a large hole in the sole of the foot. The same remarks apply to the pictures of tape-worms on p. 428, to the helminth eggs on p. 429, and to the various pictures of insects.

Neither in the description of the sand-flies nor in the chapter on kala-azar is there any mention of *Phlebotomus argentipes*, and its possible relationship to the transmission of kala-azar. Some precise information on the work that has been done in India in this connection should surely have been included, without necessarily committing the author. In the prophylaxis of kala-azar no mention is made of treatment centres, but measures of segregation alone are suggested. It is stated on p. 560 that 'Koch maintains that human tuberculosis is different from bovine. He further holds that bovine tuberculosis is not dangerous to man'. In fairness to a great figure departed, it should be stated that Koch very definitely receded from his earlier views.

The chapters on refuse and sewage disposal, water, food, soil and housing are very good; but that on vital statistics is too compressed for clarity. There are useful and helpful sections on fairs and festivals, and on camp sanitation. Several appendices are incorporated giving the duties of medical officers of health, rules regarding food adulteration and the salient features of various public health acts. One appendix gives a synoptic table for the identification of Indian anophelines.

The price, Rs. 3-8, is marvellously low, though the paper and binding have had to be sacrificed somewhat; the reviewer's copy is marred by a large number of pages of unbleached paper. Nevertheless the book is excellent value for the money, and is practical and useful in its outlook and treatment.

EPIDEMIOLOGY IN RELATION TO AIR TRAVEL.

By A. Massey, M.D., D.P.H. London: H. K. Lewis and Co., Ltd., 1933. Pp. vii plus 59, with 5 maps. Price, 7s. 6d.

THE appearance of this small book is opportune for, as far as we are aware, apart from reports of conferences this is the first publication of its kind, dealing with a problem in epidemiology that is relatively new to the world and is becoming almost daily of greater importance.

Most of the diseases discussed are naturally tropical in their incidence, and, as the book is written by a health officer of an inland English city, much of the matter is necessarily sketchy, and we cannot agree that the Asiatic distribution of plague and cholera are practically identical, as two of his maps suggest.

But, apart from slight errors in detail, the book is a valuable one as it gives a rapid résumé of the essentials regarding the danger of the spread of disease by aeroplane, and also indicates reasonable precautions that may be taken to prevent this; it is therefore recommended to health authorities whose work brings them in touch with long-distance air traffic.

NUTRITION IN HEALTH AND DISEASE FOR NURSES.—By L. F. Cooper, B.S., M.A., M.H.E., E. M. Barber, B.S., M.S., and H. S. Mitchell, B.A., Ph.D. Fourth Edition. Revised. London: J. B. Lippincott Company, 1932. Pp. xli plus 606, with 102 illustrations. Price, 12s. 6d. (Obtainable from Butterworth and Co. (India), Ltd., Calcutta.) Price, Rs. 9-6.

IN this book the authors have presented the principles of nutrition and dietetics in a very simple and lucid manner. It contains most of the recent advances on the subject and is quite up to date. It is divided into five parts. Part I deals with the principles of nutrition and has some very useful chapters on the value of vitamins of mineral salts in nutrition and health. Part II deals with food selection and contains very valuable hints on the preparation of suitable menus. This chapter will be found interesting by nurses. Part III deals with diet in disease. This is the most valuable section in the book and will be found useful both by physicians as well as nurses. In it the authors have discussed the dietetic treatment of disorders of the gastro-intestinal tract, diseases of the liver and biliary tract, over-weight and under-weight, epilepsy, arthritis, gout, diabetes, and allergic diseases, and have furnished some very important information. Part IV deals with the method of cooking for the sick and convalescent. It has numerous recipes and practical hints on cookery, and will be found useful by nurses. Part V deals with instructions to teachers regarding the use of the book.

Although primarily meant to supply the needs of the nurse, the book will be found very useful by the general practitioner as well. To those who are interested in the dietetic treatment of diseases the book is recommended.

K. V. K.

THE DIABETIC LIFE: ITS CONTROL BY DIET AND INSULIN.—By R. D. Lawrence, M.A., M.D., F.R.C.P. (Lond.). Seventh Edition. London: J. & A. Churchill, 1933. Pp. viii plus 218, with 10 illustrations. Price, 8s. 6d.

THE first edition of this practical manual, useful both to practitioners and patients, was published by the author in 1925, and the fact that within a period of 8 years the book has gone through seven editions speaks volumes for its popularity. The author's object has been to bring the modern treatment of diabetes within the knowledge of diabetic patients so as to enable them to understand and follow the rationale of the treatment prescribed by the physician, in an intelligent and effective manner. In this the author has succeeded.

The present edition of the book contains up-to-date information relating to the treatment of diabetes mellitus. On account of the present practice of giving a higher carbohydrate diet, the carbohydrate content of the 'line ration scheme' has been doubled, each black line containing ten instead of five grammes carbohydrate.

The book should prove eminently useful to those for whom it is intended.

J. P. B.

A DOCTOR TO A MOTHER: THE MANAGEMENT OF MATERNAL AND INFANT HEALTH.—By E. Holland, M.D., F.R.C.S., F.R.C.P., F.C.O.G., J. C. Jewesbury, M.D., F.R.C.P., and W. Sheldon, M.D., M.R.C.P. London: Edward Arnold and Co., 1933. Pp. 96. Price, 1s. 6d.

A Doctor to a Mother comprises a series of wireless talks broadcast by well-known experts on the management of maternal and infant's health.

Dr. Eardley Holland contributes two chapters on ante-natal care which set forth clearly the reasons which make examination necessary, the scope of the examination, and the use made of the information obtained in planning a suitable regime.

Dr. Jewesbury deals with the normal baby and its dietetic and other requirements, the precautions to be

taken to maintain and promote health, and the reasons for minor departures from health.

Dr. Sheldon is responsible for three chapters on normal physical and mental development, and some of the commoner nervous disturbances which can be prevented by careful management and training.

The style is simple and lucid, the teaching excellent and while the work cannot, and is not intended to, supplant personal contact between parent and doctor, it will form an excellent background for any additional advice the doctor may find necessary. Popular books on mothercraft in the Indian vernaculars are few and far between, but the demand is increasing and a translation of *A Doctor to a Mother* with a few minor modifications would fill the gap admirably. It is an excellent little book to recommend to mothers, since it will whet their appetites for more knowledge, and will lead them to consult the doctor or the welfare centre in time to prevent disasters.

J. M. O.

THE PHYSICO-CHEMICAL THEORY OF THE PROCESS OF THE INTERNAL DEFENCE OF ANIMALS.—By D. S. Anand, M.B., B.S. Published by the author, I. D. Hospital, Lahore. Pp. xiv plus 92.

In this report Dr. David Satya Anand has attempted to convey to his readers the main principles on which modern immunology is founded. He has given extracts from several books (thirty in number) of recognized importance, including Topley and Wilson's *Principles of Bacteriology and Immunity*, and Well's *Chemical Aspects of Immunity*. These extracts occupy the major portion of the report; the last few pages of it are, however, devoted to a description of certain experiments on antigen-antibody relationship which the author claims to have performed under very trying circumstances.

The chief object of the report, according to the author's own admission, is to elicit the sympathy of the readers and to obtain financial, laboratory and other facilities for work, through their influence. It strikes one as a queer method of appeal which, although very original, cannot be called very sound. It would have been far better if the writer had utilized the money, time, and energy that he spent on the preparation of this report in performing, on an extended scale, the experiments he thinks necessary, and had then published his results in scientific journals.

The get-up of the report is fair, but there are many grammatical and other errors which could have been easily avoided.

The writer deserves every sympathy and may be complimented for the trouble he has taken in publishing this report.

SWASTHYA AUR ROG. (HEALTH AND DISEASE.)

Written in Hindi.—By T. N. Varma, B.Sc., M.B., B.S., D.T.M., L.M., F.R.F.P.S. Published by the author, Allahabad. Pp. 895, with 407 illustrations. Price, Rs. 7. (Available from Law Journal Press, Allahabad.)

This book is written in the Hindi language. It deals with a large variety of subjects relating to the laws of hygiene and prevention of diseases, and is divided into 28 chapters.

Beginning with a discourse on the place of man in the universe and his struggle for existence, the author has admirably put before the readers the rôle of bacteria, flies, insects and parasites in the causation and transmission of human disease. The subjects of ventilation, housing, water, dietetics and exercise have been thoroughly discussed. All the preventable diseases have been described and the prophylactic measures advocated are sound and up to date. Other important diseases and congenital abnormalities have also been dealt with. Sound advice has been given as regards personal hygiene. Finally, a couple of chapters are

devoted to the question of sexual psychology, sex-hygiene and infant nursing.

The book is profusely illustrated. Most of the illustrations are original and the remaining ones have been reproduced from standard European books. The coloured plates are excellent and reflect credit on the printers.

The author is gifted with a charming style and the book he has written is a veritable store-house of knowledge. We have no hesitation in recommending it to the Hindi-reading public.

A. K. M.

BAILEY'S TEXTBOOK OF HISTOLOGY. Revised and rewritten by A. Elwyn, A.M., and O. S. Strong, A.M., Ph.D. Eighth Edition. London: Baillière, Tindall and Cox, 1932. Pp. xvi plus 746, with 529 figures in the text. Price, 31s. 6d.

This book is the work of a group of professors of the Columbia University. It is written primarily for the student and controversial discussions have been wisely avoided. With each new edition some chapters have been rewritten, so that since the first edition the book is completely changed. In this edition a new chapter on the living cell has been added; in it the subject of tissue culture has been dealt with at some length. The study of the living cell has, as the authors say, broken down the barriers between anatomy and physiology, and this chapter will add reality to the subject of histology from the point of view of the young student.

In the chapter on the various blood cells and their origin, the authors have taken Maximow's view of the unity of origin of the monocyte and the histiocyte, the former having undergone a change of function. They use the word 'monocyte' in place of the more comprehensive term 'large mononuclear', to include both monocyte and histiocyte; in view of the fact that they admit the difference in function of these two cells, it seems a pity thus to confuse the reader. However, they may take the view that the histiocyte does not normally appear in the peripheral blood, and it is with the normal that they are mainly dealing.

The book is clearly written and well illustrated, and it should prove a very useful standard textbook on histology.

L. E. N.

MACKENNA'S DISEASES OF SKIN. Third Edition. Revised and enlarged by R. M. B. MacKenna, M.A., M.D., B.Ch. (Camb.), M.R.C.P. (Lond.), M.R.C.S. (Eng.). London: Baillière, Tindall and Cox, 1933. Pp. xiv plus 506, with 149 figures and 45 plates. Price, 25s.

This book already enjoys an established reputation amongst students and practitioners as a useful guide to the diagnosis and treatment of skin diseases. It is of about the right length, neither an encyclopædia in which all the rarest conditions are described, nor a scrappy 'introduction' which contains too little to be of any value except to examinees. The third edition has been edited by Robert W. MacKenna's son. It is no mere reprint of the second edition; the subject-matter has been brought up to date and in most chapters reference is made to papers published since the appearance of the last edition, and, we are told, a number of new plates have been added. The book provides us with as good an exposition of the present-day practice and teaching of dermatology as one could want. The student who absorbs its contents should welcome a question on skin diseases in either his paper or his *viva voce*, and the practitioner who has it to refer to should never be at a loss to attach some Latin name to his patient's skin lesions or to find a new prescription to try.

This is as much as we can say in praise of the book; our quarrel is not with the author, but with the whole body of dermatologists. Admittedly, the subject is a difficult one, and most treatments very unsatisfactory, but the dermatologists do not even face the facts, instead

they revive a subterfuge which was discarded a hundred years ago by the more honest amongst the medical profession and cloak their ignorance by the application of long Latin names, the puerility of which they themselves are obviously ashamed. They apply dozens of different names to conditions with slightly varying clinical manifestations but obviously a single ætiology, and yet they will group together a variety of conditions with very divergent ætiologies and call them 'eczema'. The author of this book refers to the 'protean manifestations' of eczema, and the multiplicity of its causes, he gives a very vague definition, by which it would be difficult to distinguish eczema from other inflammations of the skin, and yet he maintains that it is a distinct disease; he may have reasons to justify this claim, but he does not give them.

Whilst dogmatism is to be deplored, it seems unnecessary to introduce, particularly without any guiding criticism, a whole series of little-used forms of treatment. For example, under the treatment of syphilis the following isolated paragraph appears—'Antimony is less efficacious than salvarsan, and may be used in the form of tartar emetic.....injected intravenously.....' It certainly is less efficacious than salvarsan, but what is the authority for assuming that it has any action at all on either the lesions or the Wassermann reaction?

We cannot close this review without reference to the very beautifully reproduced plates; the colours are very true. There are 45 of these, many of which have two figures; and they are alone worth the price that is asked for the whole book.

Annual Reports

REPORT OF THE HEALTH ORGANIZATION FOR THE PERIOD JANUARY 1931 TO SEPTEMBER 1932. LEAGUE OF NATIONS, GENEVA.

I. PERMANENT COMMISSION ON BIOLOGICAL STANDARDIZATION

This Commission met in London on 23rd June, 1931, under the chairmanship of Dr. Madsen. Its agenda included the standardization of gas-gangrene antitoxin, tuberculin, and diphtheria prophylactics.

Following its usual custom, the Commission had invited all the experts who took part in the preliminary laboratory researches to attend its meetings. They were allotted to sub-committees as follows:

The proceedings of these sub-committees may be summarized as follows:

Gas-gangrene antitoxin.—The use of active serum against *B. perfringens*, an agent of gas-gangrene (B. of Welch-Fraenkel), has tended to become general since the war. It was therefore in the interest of practitioners and producers that its potency should everywhere be expressed in terms of the same unit. That unit had to be capable of definition in terms of a standard serum which, being prepared in a stable form in quantities sufficient for distribution amongst the producing laboratories, would enable them to adjust the potency of their own serum to that of the international standard. Hitherto an antitoxin unit had been adopted only in the United States of America, but as, in practice, that unit proved to be too large, a unit one-hundredth the size was substituted for it in 1930.

The questions which the Permanent Commission on Standardization sought to solve were the following:—

(1) Can the anti-perfringens serum be assayed with sufficient accuracy?

(2) What standard should be adopted for international use?

The Commission adopted the same method of work as had previously enabled it to reach agreement on the standards used in assaying antidiphtheritic, antitetanic and antidyenteric sera. This method consists in entrusting researches to a number of laboratories, both official and private, in the countries concerned. The experimental results are communicated to the Danish State Serum Institute, which acts as a central laboratory. When the contributions thus brought together seem to point to a solution of the problem, the experimenters are invited to a conference, at which any divergencies which may still remain are easily adjusted. This is what took place at the London meeting.

The investigations undertaken at the Commission's suggestion were based on the use of two sera in the dry state, one of which was prepared by the National Institute of Health, Washington, and the other by the Wellcome Physiological Research Laboratories,

Beckenham. The relationship between the potency of two solutions of these sera, expressed in the new American units, had been carefully calculated at the Washington laboratory. The experimenters were asked, on the one hand, to repeat this assay, and, on the other hand, to determine the activity of an antitoxin of unknown potency. To facilitate the work, they were supplied with a stable preparation of toxin.

The results obtained are in agreement. In the assay of the unknown serum, 7 workers out of 8 returned values ranging from 200 to 225 new American units per c.c. As regards the comparison of the solutions of dried sera, all the assays showed an adequate equivalence.

The dry preparations of anti-perfringens serum may therefore be prepared and assayed in terms of the American standard. The Commission was thus able to recommend:

'That the standard preparation and unit adopted in the United States of America be accepted for international use, and that the "Statens Serum Institut", Copenhagen, be requested to keep and distribute the international standard.'

Toxins used in the Schick test.—The test dose used in the Schick test was originally defined as one-fiftieth part of the minimum lethal dose, for a guinea-pig, of a matured diphtheria toxin. This definition is still in use in the United States and the dosage there is therefore based entirely on the lethal action of the toxin on the guinea-pig. It is nevertheless considered to be sufficiently accurate for the practical purpose of distinguishing receptive subjects from immune subjects.

With dosage carried out on this basis, it is clear that test doses of different toxins may contain varying proportions of toxoid to toxin, and that these test doses may therefore vary rather widely in their combining powers for antitoxin. Experimentally, it is easy to show that animals with an appropriate amount of antitoxin in the blood will give a positive reaction to one and a negative reaction to the other of two toxins varying in their combining power, though injected in both cases in equal quantities representing the same fraction of the minimum lethal dose. There remained a difference of opinion as to the necessity for a supplementary adjustment of the test dose in relation to its combining power. In some countries—e.g., the United Kingdom—this adjustment was legally enforced. This additional stipulation excluded from use many toxins which would have been available on the American basis. With a view to international agreement on a definition of the test dose, the Commission studied the question of the necessity for dosage by combining power.

The Schick test was to be carried out on actively immunized individuals, convalescent cases of diphtheria, healthy individuals who had been given diphtheria.

antitoxin as a prophylactic measure, and, finally, normal individuals. The toxins were to be injected each into one arm, and there was also a control injection with the same toxins heated to 85°C. for thirty minutes.

Of the 1,457 individuals tested, the numbers of Schick-positive and Schick-negative reactors were as follows:

	Toxin A	Toxin B
Schick-positive reactors ..	594	660
Schick-negative reactors ..	863	797

The international enquiry thus showed that the number of persons classed as Schick-positive or Schick-negative depended on the properties of the toxin used in making the test. The Commission therefore recommended that, in choosing a diphtheria toxin, its combining power as well as its toxicity should be taken into account.

Diphtheria prophylactics.—What preparation of diphtheria prophylactic, preferably an anatoxin, might be adopted as an international standard, and what fraction of that standard should be used as a unit? The Commission entrusted the study of these questions to the Statens Serum Institut, Copenhagen; the Staats-Institut für experimentelle Therapie, Frankfurt-on-Main; the National Institute for Medical Research, London; the Institut Pasteur, Paris; and the National Institute of Health, Washington.

Before the study of these questions is begun, however, experimental research will have to be undertaken with a view to ascertaining, on the one hand, the length of time which must elapse between the injection of anatoxin and the test for immunity, and, on the other hand, the importance which should be attached to seasonal variations in immunity.

When these two points have been cleared up, comparative tests on the immunizing potency of different prophylactics will be carried out in accordance with a plan of research drawn up by the Commission.

Tuberculin

The question of the standardization of tuberculin has been before the Commission since 1926. Numerous comparative assays of the standard preparations in use in the different laboratories have been carried out on various occasions, and have shown that the standards were equivalent. The Commission was therefore able to recommend that the preparation of tuberculin kept at the Statens Serum Institut, Copenhagen, should be accepted as a standard for international use. The testing may be carried out by subcutaneous or cutaneous injection.

The Commission was of opinion that the question of the standardization of anti-meningococcus and anti-pneumococcus serum could not usefully be pursued at present. On the other hand, it decided to undertake a study of the standardization of sex hormones, more particularly the oestrus-producing hormone, and of certain biological products used for veterinary purposes.

To the list of products for the standardization of which it has been possible to reach international agreement under the auspices of the Commission on Biological Standardization, there have thus been added gas-gangrene (*perfringens*) antitoxin and tuberculin, in addition to the vitamins, to which reference is made below. This represents valuable progress by which practitioners and manufacturers will benefit.

CONFERENCE ON VITAMIN STANDARDS

The problem of the standardization of vitamins was taken up in 1925 by the Second International Conference on the Standardization of Biological Products, which requested Professor Poulsen to undertake a critical examination of the whole question. He reached the conclusion that only the assay of the growth-promoting factor in vitamin A might at that time have formed the subject of international agreement. Since then, our knowledge of vitamins has increased, and the time seemed to have come to resume the study of this question. A Conference on Vitamin Standards was

accordingly held in London from 17th to 20th June, 1931, under the chairmanship of Dr. E. Mellanby, Professor of Pharmacology, University of Sheffield.

At the outset, the Conference decided that, in the present state of our knowledge, the study of the fat-soluble vitamin A, the antirachitic vitamin D, the antineuritic vitamin B, and the antiscorbutic vitamin C might profitably be undertaken. It had also to take a decision on a question of principle: should the vitamin units be defined with reference to their biological action, or should they be expressed as a definite weight of the standard? The second alternative was adopted, this being in line with the precedents set by the earlier conferences, which resulted in the standardization of digitalis, strophanthus, insulin, salvarsan, and pituitary extract.

In regard to the *fat-soluble vitamin A*, the Conference recommended that, for two years, carotene should be accepted as an international provisional standard of reference, and that cod-liver oil should be held in view as a possible secondary standard.

The preparation of carotene, extracted from carrots by Willstätter's method and purified by recrystallization, will be a mixture of the two isomers the biological activity of which appears to be similar. A sample of carotene prepared in the laboratories of the countries concerned will be sent to the National Institute for Medical Research, London, which, acting as the central laboratory on behalf of the Health Organization, will be asked to undertake the final preparation of the international standard, the unit of vitamin A being equivalent to 1 milligramme of that standard.

No particular method was recommended for conducting the assay, since further progress seems to be necessary in the study of methods based on the curative action of carotene in xerophthalmia. Moreover, it is highly desirable that investigations should be made regarding the stability of carotene, both when sealed in tubes and when in solution.

The Conference decided to ask the Department of Agriculture of the United States of America to place at the disposal of investigators in other countries sufficient supplies of cod-liver oil to enable them to assay this oil in terms of the standard preparation of carotene. It is hoped thus to obtain evidence regarding the stability of vitamin A in cod-liver oil as affected by the conditions in which that oil is stored.

By a decision of the Conference, the standard for the *antirachitic vitamin D* will, for the next two years, be the solution of irradiated ergosterol at present issued from the National Institute for Medical Research, London. If, owing to the exhaustion of the reserve, it became necessary to replace this solution by a fresh standard, the equivalence of the two products would be determined by experts belonging to the following institutions:—

- Allgemeines Chemisches Laboratorium, Göttingen;
- Tierphysiologisches Institut, Leipzig;
- Food and Drugs Administration Laboratory, Department of Agriculture, Washington, D.C.;
- Biochemical Department, University of Stockholm;
- Department of Agricultural Chemistry, University of Wisconsin;
- School of Hygiene, Johns Hopkins University, Baltimore;
- Laboratoire de Physiologie de la Nutrition, École des Hautes Études, Paris;
- Pharmaceutical Society, London.

In the preparation of the future standards, irradiation with ultraviolet light must be done in ethereal solution in the absence of any traces of oxygen. The solution of the product will be made in a stable natural vegetable oil, which has given a negative test for vitamin D. The unit will consist of 1 mg. of the standard solution. When this dose is given daily to a rachitic rat for eight successive days, it produces a wide line of calcification in the metaphysis of the proximal end of the tibia and of the distal end of the radius.

(3) *Northern Rhodesia Copper Mines*.—An investigation lasting two months was undertaken by Dr. Ordman in connection with the occurrence of pneumonia in the native labourers on the various mines in the Northern Rhodesia copper belt. The investigation commenced in May, and included an intimate study of the various conditions which might have reference to the comparatively high incidence and mortality rates in pneumonia. The climatic circumstances, susceptibility to lung diseases of the different native tribes employed, conditions of native labour as regards surface and underground work, diet, feeding and compound housing arrangements were all examined in their possible bearing on the respiratory diseases incidence. The various hospitals were visited and all cases of respiratory disease clinically studied. Statistical data relating to disease incidence on these mines were analysed and deductions made therefrom as regards the epidemiology of pneumonia and allied conditions. An enquiry was instituted into the bacteriology of acute respiratory diseases in the native labourers of the copperfields, and finally a comprehensive report was presented.

From an epidemiological point of view the findings were of considerable interest. For, among the many cases of pneumonia studied bacteriologically, the pneumococcus was isolated in only two instances. It was found that the *Streptococcus pyogenes* was the organism primarily responsible for the respiratory infection. Other bacteria associated therewith to a lesser degree were the hæmolytic *Staphylococcus aureus*, the *Streptococcus salivarius* and the *M. catarrhalis*. A very unusual feature also was the complete absence of the *B. influenzae*, an organism which, in our experience of these investigations, is commonly found in acute respiratory disease.

A number of suggestions and recommendations were made with the object of diminishing the predisposing causes of pneumonia. As a result of the bacteriological examination a mixed vaccine containing representative strains of the organisms isolated was prepared for use as a prophylactic agent on the copper mines.

DEPARTMENT OF ENTOMOLOGY

From the 5th November, 1930, to the 16th May, 1931, Mr. De Meillon was attached to a special commission, headed by Professor Swellengrebel, investigating malaria in the Union. One of the facts brought to light, as a result of this work, was that the principle of 'species sanitation' could be applied in South Africa. The resulting widespread interest taken in this aspect of malaria control was very well reflected in the large number of larvæ and adults of anophelines sent in for identification.

In a more extended report to the Union Government on the results of his investigation, Professor Swellengrebel recommended that a field station for malaria be established by the Institute. A site was selected at Tzaneen, in the north-east, where a laboratory was suitably equipped. The Entomological Department

India may not be so well
the Government of the
on this report, we would like

to record an appreciation of Colonel Gill's efforts to advance the cause of public health in the Punjab.

Colonel Gill is a Neo-Sydenhamist and his remarks on the relationship of weather and economic conditions to disease are of interest. The meteorological conditions in 1931 in the Punjab were unfavourable both to epidemic plague and epidemic malaria. During the first half of the year, relative humidity was low, and rainfall was deficient, and in the second half the monsoon was normal, with no excessive rainfall in July and August. The former conditions are inimical to plague epidemics, and the latter negative the occurrence of a widespread epidemic of malaria.

The price of staple food grains continued to be low, the main cause being the decline in the export of wheat owing to the world-wide depression of trade. High prices of staple foods have in previous reports been commented on as having an adverse effect on public health, and as Colonel Gill says, it seems paradoxical to be anxious about low prices in the same connection. As a matter of fact there has been (as yet at any rate) no evidence that the peasant of the Punjab has suffered in his health from the present economic depression. As long as there is some reserve to fall back on, low food prices enable the peasant to get at least sufficient for his immediate needs.

The birth rate in the Punjab in 1931 was high, the death rate and the infantile mortality low. The rates for these calculated on the figures for 1931 were 42.7 and 26 per 1,000 of the population and 178.26 per 1,000 births respectively. The 1931 population was 23,460,267 which is 2,942,661 in excess of the 1921 population. Muhammadans increased by 14.76 per cent. in the decade, Hindus by 6.37 per cent. and Christians by 22.49 per cent. The rural population in 1931 was 86.7 per cent. of the total, as compared with 89.8 per cent. in 1921. The tendency in the decade therefore has been definitely towards urbanization.

As regards mortality, the lowest rates are in April and August and the highest in November and December. In this report 1931 followed the usual features.

Females in the Punjab up to the age of 10 have a lower death rate than males, but after this at all ages they have very definitely higher death rates than males. This is true of all the religious classes of the community. Of the chief diseases, cholera caused only 391 deaths and 706 seizures; for 4 years now the Punjab has been unusually free from cholera, but similar periods of freedom have occurred many times in the past. Such cholera as there was showed a predilection for towns, with no explosive outbreaks. Colonel Gill is of opinion that such protracted epidemics are not water-borne but due to flies and to the insanitary conditions that exist in practically all the Punjab towns. Conservancy arrangements must be improved in towns before these can hope to escape constant liability to cholera which, under present conditions, will defy all attempts at control.

Smallpox caused 3,646 deaths; there has been a steady decline in smallpox during the last few years (the present year 1932-33 has seen a distinct recrudescence however). Colonel Gill notes that there has been a hopeful increase of vaccinations especially primary. Special propaganda is necessary to reach the female population which suffers from smallpox heavily in proportion to the male population.

Plague as mentioned above was mild and confined to three districts only. It persisted in a small number of localities in the submontane tract. Colonel Gill states that there are good grounds for the opinion that plague is definitely a back number in the Punjab, but as the chart of yearly mortality shows, he is apprehensive that it may rear up its head again at any moment. He advocates continued vigilance and energy in rat destruction, though he admits that in the neighbouring Indian States, where no rat campaigns are carried out, the decline in plague has been very similar to that of the Punjab.

Malaria also was not epidemic. The solution of the problem of epidemic malaria in the Punjab lies in measures designed to prevent prolonged flooding of low-lying tracts. This has been done in parts of Lahore with marked success. The Water-logging Board is carrying out similar work wherever it is possible and has issued a set of rules and principles to be followed in the construction of canals, roads, and railways. The responsibility for urban malaria lies with municipalities, who however do not utilize the powers they have, to do much about it.

Phthisis is a scourge in the cities, though there is some uncertainty about the exact extent of its ravages. Municipalities can do something by remedying gross defects of conservancy and drainage, but the real house problem is probably a little beyond them.

Diphtheria was commoner than usual. Passive immunization was largely used in Rawalpindi, but active immunization has not yet been tried.

Leprosy is prevalent in certain areas, especially Kangra district. A special Leprosy Officer has been appointed and has done excellent work in the survey-treatment-propaganda principle advocated and carried out by Dr. Muir in various other provinces.

In the all-important matters of rural sanitation the Rural Sanitary Board gave free financial assistance for the purpose of increasing water supplies in villages located in waterless tracts; and in connection with Maternity and Child Welfare Work District Boards were given assistance to enable maternity and child welfare centres to be opened and village *daïs* to be trained. An important memorandum was drawn up setting forth the principles that should be followed in village development in the selection of village sites, layouts, water supplies, drainage and house hygiene and these are being followed in the Nili Bar Colony.

In connection with religious fairs, the interesting statement is made that incineration of night-soil is now replacing trenching. To those who have experienced the difficulties of incineration of night-soil even under disciplined conditions, this comes as rather a surprise and a description of the methods and organization would be very helpful. The activities of the Public Health Staff, the Vaccine Institute, the Epidemiological Bureau, the Chemical Laboratory, the Equipment Depot, the Educational Bureau and Health Propaganda section, are interestingly summarized. In his concluding paragraphs Colonel Gill modestly claims a share for his department for the conditions of good health pertaining during the year. In this we thoroughly agree and would again congratulate the Public Health Department of the Punjab on its alertness and activity. We wish the Director of Public Health every success in his continuation of the work of Colonel Gill.

ANNUAL REPORT ON THE MEDICAL INSPECTION OF SCHOOL CHILDREN OF THE PESHAWAR, BANNU AND DERA ISMAIL KHAN MUNICIPALITIES OF THE NORTH-WEST FRONTIER PROVINCE FOR THE YEAR ENDING JUNE 1931. PRINTED BY THE GOVERNMENT OF THE NORTH-WEST FRONTIER PROVINCE.

This report is an account of extensive and valuable work both from the point of view of immediate prevention and cure of disease as well as by the education of large numbers of children and through them their parents in elementary health matters.

The scheme of medical inspection of school children was extended to embrace all classes, *viz.* primary, middle and senior. The number of boys who were medically examined was 10,610, and the annual expenditure per boy was Re. 0-10-6. This sum is very small in comparison with the benefit received, especially when medicines were supplied to schools at a distance from hospitals; while in addition spectacles were supplied to poor children and dentists were paid merely for the intrinsic value of the work done for such children.

In Peshawar 12,462 examinations were carried out as against 6,144 during the previous year. Every boy was thoroughly examined once in every quarter.

During the first quarter of the school year 65 per cent. of the boys were examined for treatment. This percentage fell to 29 in the last quarter. The reason for this is that in the first quarter there was an influx of new students, a large number of whom came from villages. These newcomers' principal maladies were, bad eyesight, bad teeth and enlarged spleens with anæmia. All these boys had to be taught how to keep themselves clean.

It is gratifying to note that parents are more favourably inclined towards medical inspection of their children. In my last report I mentioned that one of the great difficulties in the initiation of the scheme was their total lack of interest and in fact, in some cases, open resentment against the medical authorities for even suggesting that their children needed treatment.

Medical Inspectors visited the houses of delinquent parents and explained to them why treatment of children is necessary.

'Bringing up the parent' seems to be almost more important in this Province than 'Bringing up the child'.

In the last report it was pointed out that difficulty was experienced in getting boys to attend hospital for treatment in places where schools were situated at a distance from dispensaries. This difficulty has been surmounted by supplying ordinary medicines to such schools. The medicines are in the charge of the Head Masters who give them, on the recommendation of the Medical Officer, to boys in need of them. The serious cases, however, and those requiring special medicines have still to go to the nearest hospital for treatment.

Medical Officers give lectures to every class once a quarter on hygiene, simple methods of prophylaxis of diseases, physical culture and general ideas of keeping the body and mind fit.

Uncleanliness and skin diseases.—In the first quarter 0.3 per cent. of children were found suffering from skin diseases, while in the fourth quarter only 0.2 per cent. were so suffering.

Twenty per cent. were found unclean in the first quarter as against 35 per cent. in the corresponding quarter of the last year. As a result of co-operation on the part of the school teacher, this percentage fell to seven per cent. in the last quarter.

For the purpose of combating uncleanliness separate registers are maintained by teachers who award class marks daily for cleanliness.

Dental diseases.—Twenty-four per cent. of the children examined during the last quarter required dental treatment as compared with 29 per cent. during the same quarter of the last year. This percentage includes caries of the teeth and pyorrhœa. In Peshawar 17.66 per cent. of the children suffered from dental diseases, caries 16.06 per cent., pyorrhœa 0.92 per cent., and tartar 0.68 per cent. Extractions were dealt with in hospitals but other cases were treated by private local dentists who, in a large number of cases, operated free of charge.

Affections of the ear, nose and throat, excluding enlarged tonsils and adenoids.—4.8 per cent. of the children suffered from diseases of the ear, nose and throat in the first quarter as compared with 7.5 per cent. in the same quarter of the last year. This percentage fell to 1.5 per cent. in the fourth quarter.

Enlarged tonsils and adenoids.—36.9 per cent. of the children were suffering from enlarged tonsils and adenoids in the first quarter, while in the fourth quarter this percentage was reduced to 6.6 per cent. After great persuasion 26 cases submitted to operative treatment.

The marked reduction in the percentage of sore-throats is due to the fact that children were not allowed to eat sour things, such as tamarind (*imlee*), etc. Local vendors were forbidden to sell such eatables in the schools' compounds.

External eye diseases.—Twenty-eight per cent. of the boys examined during the first quarter were suffering from external eye diseases, while in the fourth quarter this percentage fell to 5.9. This is very encouraging. The majority of these cases suffered from active trachoma.

Defective vision.—4.2 per cent. of children were found on examination to be suffering from defective vision. All these cases were corrected with spectacles excepting those suffering from diseases which would not improve even with glasses. Although there used to be great opposition to the use by children of spectacles, the parents, seeing the advantage, do not now object.

In Peshawar Municipal Schools the causes of defective vision were:—

Hypermetropia, astigmatism and myopia 4.21 per cent.; trachoma 0.54 per cent.; cataract 0.05 per cent.; corneal opacity 0.41 per cent.; and other diseases of the eye 0.03 per cent. Total defective vision in this area was 5.24 per cent.

Malaria, enlarged spleen and anaemia.—Malaria is present amongst all school children in the North-West Frontier Province. In the first quarter anaemia due to malaria was 16.23 per cent. and to enlarged spleen 7.5 per cent. while in the fourth quarter these percentages fell to 1.5 and 6.5 per cent. respectively. Last year the percentage of enlarged spleen was 11.4 per cent.

Heights, weights, chest measurements and general statement concerning the physical fitness.—A statement concerning the physical fitness of Bannu and Dera Ismail Khan school-boys of all ages, together with a comparative statement containing similar information for English boys of the same ages, is attached. The English school averages have been taken from *Lyons Medical Jurisprudence for India* by L. A. Waddell; they are for boys only. At six years of age the average height of the English school child is 3 feet 8 inches and that of the Frontier child is 3 feet 6.6 inches. The average weight of the English school child at this age is three stones and two and a half pounds and that of the Frontier child is two stones and 8.8 lbs., i.e., 7.7 lbs. lighter.

The Frontier boy at the age of six has a chest measurement in expiration of 20.8 inches and in inspiration of 22.3 inches.

At the age of six 7 per cent. of boys are of good physique and 90 per cent. of fair physique.

Vaccination against smallpox.—During the year under report 20 boys required vaccination. All of these were vaccinated.

Infectious diseases.—There was no epidemic of any infectious disease. One student in Dera Ismail Khan contracted measles.

Tuberculosis.—The following numbers of cases suffering from tuberculosis of various types were found during the year:—

(1) Pulmonary tuberculosis	3
(2) Tuberculous glands in neck	9
(3) Tuberculous sinus, foot	1
(4) Tabes mesenterica	2
(5) Cold abscess, chest	1
(6) Tuberculous sinus, neck	1
(7) Tuberculous spine	1

TOTAL .. 18

Open air classes.—The majority of school classes are regularly held outside the schools when the weather permits. Last year's remarks regarding the necessity to impart drill instruction to all primary schools do not seem to have had the desired effect as yet.

Lists of defective children.—Duplicate lists of defective children were prepared. One copy was given to the class teacher to enable him to see that the children attend hospital for treatment.

Health charts.—Class teachers conduct quarterly examinations of children for height, weight and chest measurements. The results are charted in each classroom. Diseases and defects of each child are also noted

against their names on these charts. This system creates not only a spirit of competition amongst the school children but also insures that the teaching staff takes adequate interest in the work.

Desks for primary classes.—Small desks, as recommended in the last annual report, have not been provided for the primary classes of any school. The boys still squat on the floor and this leads to bad postures.

School buildings.—It is regretted that it has not been possible as yet to do anything for the Islamia High School, Peshawar City. In the last annual report the building was condemned as being unfit for school premises. It is insanitary, dark, and in a dilapidated state. It is altogether unsuited to house children for six hours a day.

The remarks in the last reports about the Sanatan Dharam High School, Peshawar City, and the Khalsa Middle School, Peshawar Cantonment, still hold good. Both buildings are in a bad state of repair. They are dark, damp, congested, with low ceilings, and altogether unsuited for schools.

It is gratifying to note that the Municipal Board Primary School, Jahangirpura, Peshawar City, has acquired a new building.

New pucca latrines have been built in the Mission High School, Peshawar City.

The primary school latrines are insanitary and more supervision is necessary.

Both the Sanatan Dharam School and the Islamia Primary School in Bannu require re-building. Last year it was understood that both of these schools intended to acquire new buildings, but nothing appears to have been done so far.

Dera Ismail Khan.—Both the Islamia Branch No. 1 and the Vedic Primary School buildings are still bad, being ill-ventilated and dark.

General remarks.—Thirty-six surgical operations were performed on school children; these included twenty-six operations on enlarged tonsils, and five on tuberculous glands in the neck. There is still, however, great difficulty being experienced in securing the parents' consent to operative treatment for their children. This difficulty, which was the cause of no operations having been performed last year, has, as a result of a distinct improvement in the parents' attitude towards surgical treatment, been partially surmounted.

Special mention is made of the work done by Dr. Camphor, Dental Surgeon, Peshawar, in Peshawar City. He has done excellent work and has, in fact, refused payment even for the intrinsic value of work done by him. This resulted in a saving of Rs. 190 to Government. He has also volunteered to attend all the poor boys free of charge for so long as the present financial situation lasts.

On recent reports on school work in England, great stress has been laid on the importance of food in determining the health and physique of scholars and on the need for a mid-day meal. In India the Indian school boy has his first meal at 8-30 A.M. and then has nothing until about 6 P.M. This period is far too long and is definitely bad for the growing boy. In the recess in the middle of the morning he is hungry and, instead of having suitable food, he buys sweetmeats from the local vendor which are deleterious to his health.

It is proposed as an experimental measure to introduce a mid-day meal in the Khalsa High School, Peshawar City. If this be a success the measure will be extended to all schools in the Municipality. The cost per head will be about only Rs. 2 per mensem, and it is hoped that this small amount will not be grudged by the parents. This meal will be prepared at the schools.

ANNUAL REPORT OF THE EUROPEAN AND INDIAN MENTAL HOSPITALS, RANCHI, FOR 1931.

The reports of both these institutions for the year 1930 have been reviewed by us at length in our issue of January this year and as the greater part of these reports is very similar from year to year we propose

to deal with them quite briefly on this occasion. The table below gives the comparative total figures for 1930 and 1931, which show little change.

TABLE
Average daily strength

	Year	Males	Females	Total
European hospital	1930	99.90	100.71	200.61
	1931	97.82	98.59	196.41
Indian hospital	1930	1,010.05	218.08	1,258.13
	1931	1,033.34	226.07	1,259.41

In respect of the European hospital, however, one new, and we think original, form of treatment has been introduced by Lieutenant-Colonel Berkeley-Hill. This is in the form of a creed which is taught to the patients and is perhaps best explained by quoting from the report in full.

Introduction of a new feature in the form of a Creed.—A new feature in the form of a Creed was introduced during the year under review. The idea of this Creed is to re-assure patients, especially new patients, of the desire on the part of every member of the staff to devote his (or her) energy towards procuring the patients' recovery.

'The care of the Human Mind is the Noblest Branch of Medicine.'—Grotius.

CREED

'We believe in a healthy mind, in a healthy body, and we are co-operating with the doctors, nurses and the occupational therapists of the Ranchi European Mental Hospital to this end.

We recognize the goodwill and sincere interest of the Board of Trustees in the various measures ordered to restore us to health, and thus to useful and happy lives in our respective communities. We believe mental illness to be a honourable affliction, and we take pride in our efforts to regain mental and emotional vigour.

We look with undying hope towards the future, with faith in ourselves and with confidence in those appointed to assist us towards recovery. With goodwill towards all, we believe that this is a wonderful world, once we understand it. Even happier days are ahead'.

It is of course too early to form an opinion as to the value of this method.

ABSTRACTED FROM THE ANNUAL REPORT OF THE DIRECTOR OF THE PASTEUR INSTITUTE OF SOUTHERN INDIA, COONOR, FOR THE YEAR ENDING 31ST DECEMBER, 1931.

THE number of patients treated at the institute during the year was 545, an increase of 4 as compared with the figure for the previous year. Out of the 545 treated, 7 died from hydrophobia, a mortality rate of 1.28 per cent. At the close of the year 28 patients remained under treatment.

Advice is occasionally sought on the question whether treatment is necessary in the case of persons who have drunk the milk or have eaten the meat of animals suspected to be rabid. If the milk has been boiled and the meat cooked before use, treatment is not advised.

Simple's carbolized sheep vaccine was in use throughout the year. No marked reaction was noted in any of the cases treated with 5 per cent vaccine. No complications of any sort, nor any paralytic accidents have followed the treatment.

Antirabic vaccine for treating 9,325 persons was issued to the centres during the year under report. Of these, 8,056 are reported to have received a complete course of treatment; and there were 60 deaths among

them, a mortality rate of 0.74 per cent. Of the 60 who died, 2 were Europeans and the rest were Asiatics.

Out of the 8,601 cases treated at the institute and at the centres during the year, 8,130 were dog bites, 189 were jackal bites and 42 were fox bites.

Jackal bites account for nine out of the sixty-seven deaths. Fox bite accounts for one death and the remaining fifty-seven deaths are all from dog bites.

In three cases, the incubation period was very short, 16 days in one case treated at Tanjore, 16 days in another treated at Mangalore and 17 days in the third treated at Madura; all these three deaths were from dog bites.

In three other instances, the incubation period was very long, 247 days in a case of jackal bite treated at Cocanada, 222 days in a case of dog bite (European) treated at Lallaguda and 190 days in another case of dog bite treated at Salem.

The mortality from hydrophobia in the rural areas of the Presidency continues to be high and the figure for 1931 is higher than that in any of the preceding years. Though the antirabic treatment is decentralized to a very great extent in this Presidency, still persons in rural areas are not aware of the treatment given in Head-quarter Hospitals. More intensive propaganda work in the rural areas on the value of antirabic treatment is being carried out. The demand for vaccine is steadily on the increase. Training in the technique of antirabic treatment was given to 30 government medical officers and also to 14 medical officers from Native States and railways during the year 1931.

Three hundred and seventeen brains of rabid or suspected-rabid animals were sent to this institute for examination, by veterinary surgeons in the Presidency and Native States. We believe this figure could be much larger if veterinary surgeons would pay special attention to this important line of work.

During the past years, we have, in addition to antirabic work, undertaken to help the hospitals and medical practitioners in the Nilgiris District by doing their clinical and bacteriological work. We believe this work is being more and more appreciated by those who send their specimens to us for examination. The figures for 1931 are an increase on those of 1930.

During the past few years many improvements have been carried out at the institute. The institute is now provided with a very fine set of animal rooms where rabbits, guinea-pigs and pigeons are kept under perfect sanitary conditions. Runs have been erected for these animals to live under natural conditions. As a result of breeding under such healthy conditions, our stock throughout the year has been a healthy one and we have been able to supply other institutions with animals. During the year 1931, we supplied a large number of rabbits and guinea-pigs to various places from our surplus stock. Accommodation for sheep has also been provided, but this will have to be increased in the next year owing to the exclusive use of sheep for the preparation of antirabic vaccine and also on account of the higher dosage treatment being introduced.

In the year 1930, a cold chamber 'Hall's Patent' was erected at a cost of Rs. 10,733 and the work was carried out by Messrs. Marshall and Sons, Ltd., Madras. It was brought into use during the year under review.

Correspondence

INDIAN MALE NURSES

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I would like to bring to your notice the question of the employment of trained Indian male nurses in government and other hospitals.

Our C. M. S. Men's Hospitals (in Peshawar, Burma, D. I. Khan, and Quetta) are now training-schools for male nurses. We give selected boys solid teaching in anatomy, hygiene, and nursing (theoretical and

practical) for three years, and after each year they have to pass an examination set by the North Indian United Board of Examiners from mission and other hospitals.

These papers are not easy and the standard for pass marks tends always to get higher.

Our aim is to turn out boys fully qualified to be nurses and I think we may say that in this we have succeeded. Should they wish to qualify as 'compounders' they must take another course extending to two years, with an examination at the end of each year set by the same Board. Should they be successful, another certificate is then issued to them.

We feel that those thus equipped and who have certificated in both nursing and compounding are safe to be set free to make their own living, whether in private practice or in institutions, and instead of being a danger to their fellow-countrymen can serve them safely and efficiently.

But the difficulty is to get them employment after they are qualified. The military hospitals will not take them unless they start at the bottom of their ladders, and so far civil hospitals have not seen their way to take them, as the civil authorities say they prefer to take their own men.

We are very anxious that you should recognize our certificates and employ our boys as fully-qualified nurses and compounders, giving them the pay to which they are entitled as such.

We feel we are doing a real service for India in training male nurses and compounders and it would be disastrous if their training were to cease; but cease it must, unless we can obtain employment for those already trained.

Government and other hospitals may be glad to hear of these male nurses trained at our mission hospitals and I should be delighted to recommend several who are looking for employment.

Yours, etc.,

H. T. HOLLAND, M.B., B.S. (U. Edin.),
F.R.C.S. (Edin.).

C. M. S. HOSPITAL,
QUETTA,
16th March, 1933.

THE TREATMENT OF ACNE

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I shall be glad if you will publish the following in the next issue of the *Gazette*:—

A friend of mine has suffered from acne vulgaris for two years. Though many remedies have been employed, none has effected a cure, and so the acne and the ugly scars caused thereby still prevail. Will some member of my profession be kind enough to suggest a remedy for the removal of the acne and scars.

Yours, etc.,

P. H. BHATT, D.A.M. (Baroda Government).

LOKOPYOGI DISPENSARY,
DOLARANA'S VASNA (MAHIKATHA),
23rd February, 1933.

[Note.—This letter was submitted to Lieutenant-Colonel H. W. Acton, C.I.E., I.M.S., Director of the Calcutta School of Tropical Medicine, who has given us the following note:—

The treatment for acne vulgaris consists in the proper removal of the scales and plugs from the sebaceous-gland mouths. This can be done by the use of plenty of soap and hot water, or by using ether soap consisting of one part ether, one part alcohol and one part soft green soap. A lotion consisting of lotio alba, zinci sulphas and potassa sulphurata, 20 grains each in an ounce of water, should be lightly dabbed on to the face and, when dry, rubbed into the skin by the fingers. The lotion should at first be used twice a day and then

once, sufficient to produce hyperæmia and desquamation of the cheek. If the reaction is excessive a little cold cream can be put on at night. The scalp should also be attended to for seborrhœa.—EDITOR, I. M. G.]

COMPARATIVE NOTES ON THE CRYOSCOPY OF MILK

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—With reference to my paper entitled 'Comparative Notes on the Cryoscopy of Milk' which appeared in the *Indian Medical Gazette* of January 1933, I have had a number of enquiries as to the exact significance of the cryoscopic determination when applied to the adulteration of milk in the tropics. This question has already been answered in a paper published from this laboratory in the *Analyst*, 1932, LVII, 449. As a result of systematic study of a large number of samples of both cow's and buffalo's milk, from herds and from individual animals, over a period of eleven months (April 1930 to March 1931), it is shown that wherever possible cryoscopic examination of the milk supply is of the utmost importance, since the addition of water to buffalo's milk, so that the lower standards for cow's milk (i.e., for fat and solids-not-fat) are complied with, cannot escape detection, if the freezing point of the sample is investigated.

Subsequent experience has emphasized the importance of the method and its utility in meeting the many difficulties of a dual milk supply that arise in the East.

I would also bring to your notice that in the original typescript of my article 'Observations on the Composition of Butter Imported into Burma', published in your issue of June 1932, a typing error escaped my notice. The word 'importing' should read 'exporting' in the second line. The error is fairly obvious from the other descriptive details given.

Yours, etc.,

E. H. BUNCE, F.I.C., F.C.S.,
Public Analyst to the Government of Burma.

HARCOURT BUTLER INSTITUTE
OF PUBLIC HEALTH, RANGOON,

Service Notes

APPOINTMENTS AND TRANSFERS

BREVET-COLONEL H. H. THORBURN, C.I.E., an Agency Surgeon, is posted as Civil Surgeon, Ajmer, and Chief Medical Officer, Rajputana, with effect from the forenoon of the 17th February, 1933.

Brevet-Colonel C. A. Gill, R.A.S., Officiating Inspector-General of Civil Hospitals, Burma, is confirmed in that post, with effect from the 18th February, 1933.

The Viceroy and Governor-General has been pleased to make the following appointment on His Excellency's personal staff, with effect from the 28th February, 1933:—Lieutenant-Colonel A. H. Proctor, D.S.O., M.S., to be Honorary Surgeon, vice Major-General C. A. Sprawson, C.I.E., tenure expired.

Lieutenant-Colonel H. E. Stanger-Leathes is appointed Honorary Surgeon to The King, and promoted Brevet-Colonel, vice Major-General C. Hudson, C.B., C.I.E., D.S.O., 24th September, 1932.

Lieutenant-Colonel A. H. Proctor, D.S.O., Surgeon-Superintendent, Presidency General Hospital, Calcutta, is appointed to officiate as Surgeon-General with the Government of Bengal during the period of the leave granted to Major-General W. V. Coppinger.

Lieutenant-Colonel R. H. Candy, Civil Surgeon, Ahmedabad, to be Civil Surgeon, Poona, with attached duties, vice Major S. R. Prall, proceeding on leave.

Lieutenant-Colonel W. C. Spackman to officiate as Superintendent, J. J. Hospital, Bombay, in addition to his own duties.

Major H. E. Murray is appointed to act as Surgeon-Superintendent, Presidency General Hospital, Calcutta, with effect from the date he takes over charge, *vice* Lieutenant-Colonel A. H. Proctor.

Major W. H. Crichton is appointed substantively to be an Agency Surgeon, under the Government of India in the Foreign and Political Department, with effect from the 5th February, 1933.

Major B. G. Mallya is appointed until further orders to act as Superintendent, Campbell Medical School and Hospital, Calcutta, with effect from the date he takes over charge, *vice* Major S. N. Mukherji, granted leave.

The services of Major G. Verghese are placed temporarily at the disposal of the Government of Bihar and Orissa, for employment in the Jail Department, with effect from the date that he assumes charge of his duties.

Major J. Rodger, M.C., Civil Surgeon, Sibi, is appointed temporarily to officiate as Residency Surgeon and Chief Medical Officer in Baluchistan, in addition to his own duties, with effect from the afternoon of the 13th February, 1933, and until further orders.

Major H. Williamson, M.B., on return from leave resumed charge of the duties of the Civil Surgeon, Quetta, with effect from the forenoon of the 16th February, 1933.

Major F. R. Thornton, M.C., Officiating Civil Surgeon, Nasik, to be Civil Surgeon, Ahmedabad, with attached duties, *vice* Lieutenant-Colonel R. H. Candy.

The services of Captain H. D. R. Zscherpel are placed at the disposal of the Government of North-West Frontier Province, for employment in the Jail Department, with effect from the date on which he assumes charge of his duties.

The undermentioned appointments are made:—

To be Captains (on probn.)

W. J. Mody, 1st February, 1933, with seniority 6th December, 1932.

A. E. Kingston, 1st February, 1933.

To be Lieutenants (on probn.)

1st February, 1933, with seniority 1st February, 1932

J. D. Murdoch.

G. B. Thomas.

A. T. Andreasen.

1st February, 1933

J. M. Selater.

D. R. Tweedie.

C. F. Garfit.

J. W. Richmond.

G. S. N. Hughes.

A. D. Barber.

David Kenneth Llewelyn Lindsay, 1st February, 1933, with seniority 1st February, 1932.

LEAVE

Major-General W. C. H. Forster, C.I.E., V.H.S., Surgeon-General with the Government of Bombay, is granted, preparatory to retirement, leave on average pay for 2 months and 24 days followed by leave on half average pay for 28 days, with effect from the 28th March, 1933.

Major-General W. V. Coppinger, C.I.E., D.S.O., Surgeon-General with the Government of Bengal, is granted combined leave for 8 months, with effect from the 15th March, 1933, or subsequent date from which he may avail himself of it.

Lieutenant-Colonel H. W. Acton, C.I.E., Director and Professor of Bacteriology and Pathology, School of Tropical Medicine, Calcutta, is allowed leave on average pay for the period from the 8th April to the 15th April, 1933, and from the 15th July, 1933, to the 18th November, 1933, sandwiching the summer vacation of the School of Tropical Medicine, Calcutta, for the year 1933 for the period from the 16th April to the 14th July, 1933.

Lieutenant-Colonel T. C. Boyd, Principal, Medical College, and Superintendent, Medical College Hospitals,

Calcutta, is allowed leave for the period from the 6th April to the 22nd July, 1933.

Lieutenant-Colonel S. S. Vazifdar, Professor of Medicine and Clinical Medicine, Grant Medical College, and Physician and Superintendent, J. J. Hospital, Bombay, is granted leave for 8 months out of India, with effect from 13th March, 1933, or the date of availing.

Major S. N. Mukherji, Superintendent, Campbell Medical School and Hospital, Calcutta, is allowed leave for 8 months out of India or Ceylon, with effect from the 9th March, 1933, or the date of availing.

Major S. R. Prall, Officiating Civil Surgeon and Superintendent, B. J. Medical School, Poona, is granted leave for 4 months combined with furlough for 8 months, with effect from the 1st April, 1933, or subsequent date of availing.

PROMOTIONS

Captain (provl.) (on probn.) to be Major (provl.) (on probn.)

W. Aitchinson, M.C. Dated 20th December, 1932.

Lieutenants to be Captains

S. M. Kharegat. Dated 15th July, 1932.

R. C. Dracup. Dated 6th November, 1932.

Lieutenants (on probn.) to be Captains (on probn.)

A. K. Gupta. Dated 15th July, 1931.

Hoe Min Sein. Dated 26th January, 1933.

Note.—The provisional promotion of the undermentioned officers to the rank of Captain is confirmed:—

Captain (provl.) (on probn.) J. Singh.

Captain (provl.) (on probn.) K. Jilani.

Lieutenants to be Captains (provl.)

A. B. Guild. Dated 4th February, 1933.

A. W. West. Dated 3rd February, 1933.

RETIREMENTS

Colonel W. H. Leonard, K.H.P. Dated 12th February, 1933.

Lieutenant-Colonel J. F. Boyd. Dated 31st January, 1933.

Notes

MODIFICATION OF KIRSCHNER'S STIRRUP

By N. A. KINNEAR, M.B., B.Ch.

This modification of Kirschner's stirrup, for use in his system of piano-wire extension of fractures, seems to have advantages over some other types of stirrup.

The threading of the wire through the stirrup is simple. It is impossible to twist, and so fracture, the wire while tightening it. After the wire has been tightened it is securely and rigidly held in the stirrup by the end-piece locknuts. The stretcher is detachable and only one is necessary for any size or number of stirrups, expense being thus reduced.

There are two alternative sizes of end-piece nuts and five sizes of stirrup to suit the olecranon, the tibial tubercle, the calcaneum, or the lower end of the femur. In practice, I think, it will be found that two sizes of stirrup will be sufficient.

The instrument is reasonably priced and has been made for me by Messrs. Down Bros.

RADIOSTOL AND RADIOSTOLEUM

RADIOSTOL

RADIOSTOL is the original British irradiated ergosterol; it was issued for medical use in February 1927.

Until Radiostol was made available for medical use, the population of the world depended for its requirements of vitamin D upon the intake of the vitamin through the medium of food and upon the action of the sun's rays on the skin—the presence of minute traces of ergosterol in the skin of human beings and of animals making this natural method of production possible. The supply of vitamin D, therefore, was often inadequate and always uncertain; hence the production of Radiostol by the action of ultraviolet light upon ergosterol, with the consequent availability of a supply of vitamin D more than sufficient to cover all requirements, is of paramount importance in the maintenance of health, particularly in early life.

Radiostol, in the form of solution or pellets, is vitamin D standardized and exhibited for use in medicine; in fact from the time of its first issue Radiostol has been manufactured under scientific control, and its vitamin-D activity has been maintained at a definite standard.

The unitage adopted for expressing the activity of Radiostol is that described by the Medical Research Council, London. Radiostol is standardized in terms of the standard preparation of irradiated ergosterol issued by the Medical Research Council which contains 1,000 units vitamin-D activity per c.cm. This standard has been adopted recently for international use by the Permanent Standards Commission of the Health Organization of the League of Nations (*see p. 295*). Thus the potency of Radiostol is already expressed in terms of the International Standard. The tests are carried out on rats made rachitic by being fed on appropriate diet; the criterion used is the deposition of calcium in the cartilage at the proximal end of the tibia and the distal ends of the radius and ulna (the 'line' test).

The normal function of vitamin D is to control calcium and phosphorus metabolism, and it is now established that correct calcium and phosphorus metabolism is possible only when the available vitamin D is adequate; any increase in the calcium and phosphorus intake has little effect upon the development of bones and teeth when there is a deficiency in the vitamin-D absorption.

RADIOSTOLEUM

Radiostoleum supplies vitamins A and D in accurately-measured quantities and in the scientifically-balanced proportions in which it has been shown by experiment, and confirmed in clinical practice, that they can be assimilated to the best advantage. The proportions in which these vitamins occur in any particular product in nature is not constant, and there is no correlation between the vitamin-A value and the vitamin-D value of the natural sources of these vitamins. It has, in fact, been shown that one sample of cod-liver oil may be rich in vitamin A, but poor in vitamin D; another may show a high vitamin-D, but a low vitamin-A, content.

The vitamin A in Radiostoleum is present as an accurately-measured portion of a purified concentrate made by a special process evolved in the B. D. H. laboratories; the vitamin D is a measured quantity of pure crystals of this vitamin.

Radiostoleum is standardized to contain vitamin A and vitamin D in the following proportions:—

Liquid—

Vitamin A : 500 blue (Carr-Price value).

Vitamin D : 3000 International units of antirachitic activity per gramme.

Capsules—

Vitamin A .. 1000 blue (Carr-Price value).

Vitamin D .. 1200 International units of antirachitic activity per capsule.

Radiostoleum is the original concentrated preparation of vitamin A and vitamin D used in medicine. In fact, Radiostoleum is the product through the medium of

which the 'anti-infective' action of vitamin A was established.

In their original experiments in the Jessop Hospital, Sheffield, Mellanby and Green found that the administration of massive doses of Radiostoleum produced distinctly beneficial effects in cases of puerperal septicaemia; later the value of Radiostoleum in the prophylaxis of puerperal septicaemia was established definitely by these same workers who, treating 275 pregnant women with Radiostoleum whilst keeping 275 as controls, found that of the women treated with Radiostoleum only 1.09 per cent. developed puerperal morbidity after delivery, whilst 4.73 per cent. of the controls became infected.

McCarrison also used Radiostoleum in his experiments in India, in which he found that by its administration it was possible to maintain the integrity of the epithelial linings of the body, particularly those of 'the respiratory passages, the urinary tract, the reproductive tract, the conjunctiva, the nasal passages, the ear, and the ducts of organs'.

Copies of a booklet describing the above products will be supplied free of charge to any member of the medical profession in India on request from one of the B. D. H. representatives whose names and addresses are as follows; Henry S. Clark & Co., 27/4, Waterloo Street, Calcutta, and Byram Mistry, 109, Parsi Bazar Street, Fort, Bombay No. 1.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

As misunderstanding still appears to exist, we should like to point out again to our readers and advertisers that the "*Indian Medical Gazette*" is owned and published by Thacker's Press & Directories, Ltd. Hitherto, Thacker, Spink & Co., now in liquidation, have been the selling agents; this work is now being undertaken by Thacker's Medical Book Dept., Box No. 54, Calcutta.

THE PATHOLOGY OF ELEPHANTIASIS OF FILARIAL ORIGIN

By HUGH W. ACTON, C.I.E.

LIEUTENANT-COLONEL, I.M.S.

Director, Calcutta School of Tropical Medicine,
and

S. SUNDAR RAO, L.M.P.

Filariasis Research Worker,
Calcutta School of Tropical Medicine

THE term 'elephantiasis' was first used by Celsus to indicate leprosy, and later by Galen (130 to 200 A.D.) to indicate both leprosy and true elephantiasis. A third disease Madura foot was also generally confused with leprosy and elephantiasis until about the eighteenth century. In 1750, Hillary gave a full and lucid account of the evolution of the large leg of elephantiasis, wherein he clearly differentiated this disease from leprosy. The classical researches of Danielssen and Boeck in 1848 on leprosy, and those of Vandyke Carter in 1860 on mycetoma, established clearly the nature of and distinction between these three diseases. The aetiology of elephantiasis was further elucidated by the discoveries of the microfilariae by Wucherer in 1866 and Lewis in 1872, and the adult filarial worms and their abodes by Bancroft in 1876. About the same time, Manson carried out pioneer investigations in filarial infection in China. Following Fedtschenko, who first demonstrated in 1870 the rôle of cyclops as the intermediary host in the transmission of guinea-worm in man, Manson made the memorable discovery in 1878 that the mosquito was the carrier of filarial infection. By the close of the nineteenth century, while researches were being carried on to establish the true parasitic origin of the filarial diseases, the low microfilaria rate in those with elephantiasis puzzled many observers and considerable opposition was therefore raised to the acceptance of its parasitic origin.

Even in the present state of our knowledge there appears to be some confusion among the writers on the subject regarding the pathological signs of the infection, and several diseases of non-filarial origin are often included under the heading of elephantiasis. Cases of dermatolysis, hypopituitarism and vulvar growths of septic origin, which also show signs of pachydermia, are often mistaken for elephantiasis of filarial origin and are described as such. Any condition which is capable of producing obstruction of the lymphatic system may result in symptoms similar to those produced by filarial infection. The distinction between elephantiasis of filarial origin and elephantiasis nostra was not clearly recognized till recently, and it was suggested by

some investigators that the two diseases were of the same origin and that the presence of microfilariae in the peripheral blood of the former in the early stage of the disease was merely a coincidence.

Regarding the aetiology of elephantiasis of filarial origin also, we often notice among the investigators an imperfect understanding of all the factors which are responsible for the production of the disease. For instance, one or two recent workers appear to think that all the pathological conditions observed in all cases of filariasis are attributable to the presence of the parasite alone. The importance of secondary infection in the causation of filarial lymphangitis is altogether ignored. Such a view is a priori contrary to the bacteriological findings of various investigators in this field. Extensive observations made by us during the last ten years definitely show that while the worm (*Wuchereria bancrofti*) is primarily responsible in all cases for the damage to the lymphatic system, the pathological conditions in a large number of advanced cases of elephantiasis are mostly due to the secondary bacterial infection. This question was considered in detail by the authors in the paper 'Kataphylaxia in filariasis' (1929). The production of a toxin by the adult female parasite was for the first time demonstrated by these authors in the above paper. A distinct eosinophil reaction in the lymphatics was observed in the region of the anterior end of the worm where the vulva is situated, while it was not perceptible in the tail region. The authors were also the first to record cases of urticaria which were purely filarial in origin. That the liberation of this toxin was responsible for the production of allergic symptoms, such as periodic headache, migraine, and slight rise of temperature, in filarial patients was clearly recognized and was mentioned in this paper. The importance of the susceptibility factor was emphasized as being responsible for the differences in sensitiveness to the toxin in regard to allergic manifestation. A sentence from one of our previous papers (1931) may be quoted here. 'There is a definite type of lymphatic obstruction which is helminthic in origin and can be proved to be so on definite geographical, epidemiological and pathological evidence as due to *Filaria bancrofti*'. Although great stress was laid on the helminthic origin of the infection as is evident from the above, the possibility of 'superimposed septic infection as the result of a lowering of the local defence mechanism' was not overlooked.

A common mistake that is still prevalent among practitioners is to look for microfilariae in the blood in cases of elephantiasis. It is not yet generally understood that by the very nature of the infection it is not always possible to find the microfilariae in the blood, especially when elephantiasis is the result of lymphatic block by the adult worms. The microfilaria which is in a sheath is incapable of

independent movement and is carried by the normal flow of lymph to the blood stream, so that when there is obstruction of the lymphatic vessel they are not able to reach the blood, with the result that the microfilaria rate is low in cases of elephantiasis.

Another fallacious notion which is prevalent is that the œdema due to other causes can be differentiated from that due to elephantiasis by the pitting-on-pressure test. Although elephantoid skin does not pit on pressure in the later stages, such pitting on pressure does occur during the early stages of the disease, so that this diagnostic feature is misleading.

It is therefore proposed to give in this paper an account of the pathology of elephantiasis and its gradual development from the time the filarial worms live in the lymphatics without any apparent injury to the human system.

It is convenient to consider the pathology of filariasis under the two headings, (a) that due to the filarial toxin, and (b) that due to the secondary infection. The clinical symptoms and the various factors, such as individual susceptibility, intensity of infection, etc., which influence the types of lesions are discussed.

(a) DUE TO FILARIAL TOXIN

Production of signs and symptoms

A certain percentage of the population in an endemic area harbour the filarial worms for several years without apparently suffering injurious effects, or manifesting signs or symptoms of disease; these people thus act as carriers of the infection. The adult filarial worms live in the main lymphatics and in the hila

of the glands draining the extremities, and the sheathed embryos, as they are discharged by the adult female into the lymphatic vessels, are carried to the blood stream, provided there is no obstruction to their passage. In many instances, however, the adult worms and embryos are found lying on the distal side of an enlarged or fibrosed gland, so that the embryos are not able to reach the blood stream. An interesting case of this description may be recorded here :

B. S., Hindu, male, aged 35, was admitted into the Carmichael Hospital for Tropical Diseases for enlarged inguinal glands (left). Although no microfilariae were present in the blood, clinical examination pointed to a filarial infection of the inguinal glands. The glands were excised under local anaesthesia and three adult filariae actively coiling and uncoiling were found in one of them. The worms were separated out and the glands were imbedded for sectioning. Serial sections of these glands were cut and in these many more mature filariae were found in the lumina of the lymphatic vessels (*vide* figures 1 to 3). It is interesting to note that, although the worms recovered from these glands were quite mature and full of embryos, no microfilariae were demonstrable in the blood of the patient.

There have also been other patients in whose lymphatics and glands mature parasites were found and whose blood did not show microfilariae.

Fig. 1.—Photomicrograph of gland section showing the adult filaria.

Fig. 2.—Photomicrograph of gland section The adult filaria is seen in section.

Microfilaria rate

It is seen from the above that blood examination does not always give a true indication of

such patients for any considerable length of time. Such cases are therefore of interest as they have been under our close observation for

Fig. 3.—Photomicrograph of gland section showing adult filaria in section.

the incidence of filarial infection in a given population and yet for practical purposes the microfilaria rate may be taken as a guide to estimate the amount of filarial infection in a population. The microfilaria rate varies from area to area, and even in different wards of the same town. The factors which influence these variations will be dealt with in a later part of the paper. Table I shows the microfilaria rate among the healthy population of Calcutta. These observations are based on one single examination of a thick smear of the peripheral blood taken at midnight. We have now under our observation several persons who have shown microfilariae in their peripheral blood for the last ten years. Periodical examination of the peripheral blood taken during the night in these cases has shown the presence of embryos on every occasion but so far in none of them has there been any manifest sign or symptom of filarial disease. Several of these belong to the staff of the School of Tropical Medicine.

It may be mentioned that though filariasis is endemic in several parts in India there is so far no record of the results of observation of

TABLE I

Microfilaria rate of Calcutta city (based on a total examination of 2,922 persons from jails, hospitals, hostels and the public during 1927-1933. They include persons of all nationalities and of both sexes)

a long period. A large number of other persons in Calcutta in whom occasional blood examination has shown the infection have been living free from filarial disease for a long time. These cases are not referred to here as continuous observation for a sufficiently long period has not been possible.

Moderate eosinophilia the result of filarial toxin

From a study of the eosinophil response in filarial infections it has been found that the total eosinophils range from 400 to 800 per e.mm. A careful study of this reaction has also been made in the different stages of filarial diseases and the results are tabulated on the previous page. The total and differential counts were made in all the cases at about the same time of day. Tables II and III show the total eosinophil counts in cases of filariasis with microfilariae in blood and those without microfilariae. From the tables it will be seen that, when there is no obstruction and microfilariae are present in the blood, there is a constant high eosinophilia indicating the leakage of toxins into the peripheral blood. This question has been dealt with by us in detail in a previous communication (1929). In the early stages of filarial diseases, where there is partial obstruction, the average eosinophilia shows a distinct decrease. In elephantiasis where the lymphatic obstruction is complete there is no indication of the toxin in the blood and the eosinophil count is practically normal. In such cases the parasite is dead, and either absorbed or calcified.

Anaphylactic symptoms

In persons who harbour filarial worms anaphylactic symptoms due to filarial toxin are sometimes observed. The patients may suffer from periodical headache, migraine, urticaria, pain in the joints and muscles, small rises of temperature, 99°—99.8°F., etc. In an earlier communication cases of urticaria due to filarial toxin have been reported by us (1930). The following additional cases may be mentioned here:

B. B. M., Hindu, male, aged 37, suffering from migraine for the last 1½ years, attacks appear periodically once a fortnight or once a month; attacks last for 24 to 36 hours at a time; no fever; microfilariae present in the peripheral blood; no other focus of infection present. Total eosinophils 600 per e.mm.

X, Anglo-Indian, male, aged 12, admitted for daily rises of temperature between 99°—99.8°F. for the last two and a half months. Blood culture, Widal reaction, and stool culture—negative; microfilariae present in the peripheral blood; eosinophils 500 per e.mm.; symptoms cleared up with soamin treatment.

T. S., Hindu, male, aged 45, complained of pain in the muscles and joints including small joints of the fingers. The attacks appeared off and on for one year; no definite periodicity noted; examination of teeth, gums, throat revealed no abnormality; stool and urine examination did not show any infection. Microfilariae present in the peripheral blood. A month after the discovery of microfilariae in the blood, the dorsum of the left hand was swollen; a lymphatic cyst was opened and lymph with microfilariae in it drained from this. The blood did not show any microfilariae at this stage.

Anaphylactic symptoms are generally observed during the early stage of filarial infection in susceptible persons. In elephantiasis the obstruction is at the inguinal, the axillary or the epitrochlear region. As the main lymphatic is blocked the toxin is not able to reach the blood and allergic symptoms are therefore localized or absent. The toxin acts locally on the tissue cells and increases their permeability with the result that static oedema develops.

Dermal tests as evidence of toxin

Several attempts have been made in recent years to evolve a satisfactory dermal test to detect filarial infection in the human system. Owing to the difficulty of obtaining adult worms it has not been possible till now to carry out these tests with the *Wuchereria bancrofti* antigen. The tests are therefore carried out with the antigen of allied species. Taliaferro and Hoffman (1930) and Hamilton Fairley (1931) have reported promising results with *Dirofilaria immitis* antigen. With a view to diagnosing the presence of filarial infection, the above tests were carried out on a number of persons in our laboratories. In our earlier experiments the antigens used were prepared from adult guinea-worms, from embryos of *Wuchereria bancrofti*, and from hydrocele fluids with and without filarial embryos. In a series of 78 cases in which these tests were carried out the results were uniformly positive, both in the infected cases and in the controls, with every one of these antigens. We have now obtained *Dirofilaria immitis* antigen from Dr. Le Sueur of Sarawak, Borneo, and the results obtained with this antigen may be briefly noted here.

Fairley's technique of the preparation of antigen was followed and a 1 per cent saline extract of dried powdered dirofilaria antigen was prepared as follows:—The powdered antigen was incubated in sterile saline for two hours at 37°C., the mixture being shaken from time to time. It was then filtered through a Whatman no. 1 filter paper and a Buchner filter, and then sterilized by passing through a sterile Seitz asbestos filter. The filtrate was put up in ampoules and stored in the cold chamber till required for use. Using the extract in quantities of 0.25 e.cm. we found that the antigen produced severe reactions and so the extract was diluted to 0.5 per cent, and 0.1 e.cm. given. The latter dilution was maintained as a standard antigen for all the cases tested. The injection is generally given in the forearm, an injection of physiological saline serving as a control.

Over 250 dermal tests were carried out with this antigen. These were done on cases of filarial infection in its different stages, viz, acute filarial lymphangitis, elephantiasis of the extremities, genitals and breast, filarial abscess, adenitis, varices, cysts and chyluria. There were also four cases of guinea-worm infection. The control cases included, besides healthy normals, cases of kala-azar, epidemic dropsy,

Naga sore, malaria, and other helminthic infections, such as by ascaris, hook-worm and tape-worm.

Most of the filarial cases showed a positive reaction, but, surprisingly, a few cases of ehyluria, heavily infected with microfilariae in the blood, showed no reaction at all. In one patient suffering from filarial cysts four tests were carried out on different occasions; all were negative excepting the second test which showed a very mild positive reaction. As this second test was done shortly after a puncture of a cyst that contained adult filariae was made for examination, it is possible that the release of toxins into the general system by the puncture might have given the slight positive result. The reaction was negative both before and after the cysts were excised.

Signs of obstruction

It is well known that among infected persons living in endemic areas a few develop signs of obstruction even at a comparatively early stage of the infection. On the other hand there are several who harbour the parasite but do not show any manifestations of obstruction for a long time. A few cases of the above types that have been under our observation are mentioned below :

(1) K. B., Hindu, male, aged 28 years: No evidence of filarial infection when examined in 1927. During 1929 a casual examination of the blood revealed microfilariae in it. He suffered from orchitis once every 2 to 3 months during 1929-30.

(2) A. G., Sepoy, Mohammedan male, aged 21 years, native of North-West Frontier Province (non-endemic area); stationed at Dinapur, Behar (endemic area): Developed lymphatic obstruction of the inguinal region due to filarial infection after 18 months' stay.

(3) M. O., European, male, aged 24 years: First visit to India 2 years ago; residing in Kidderpore, Calcutta (endemic area), for last 2 years. First sign of filarial infection (lymphangitis left leg) noticed six months ago.

(4) M. N. M., Hindu, male, aged 40 years: Occasional examination of peripheral blood during the last ten years showed the presence of microfilariae. No signs or symptoms of filarial disease present.

(5) S. M. J., Hindu, male, aged 48 years: Microfilariae in blood were present on every occasion we examined it during the last seven years. No sign or symptom of filarial disease up to date.

(6) S. R., Hindu, male, aged 28 years: Blood examination for microfilariae was carried out twice during 1930, seven times at varying intervals during 1931-32 and in February 1933; microfilariae were found on every examination of the blood. Patient shows no signs or symptoms of lymphatic obstruction.

Individual susceptibility, therefore, is an important factor in the manifestation of signs and symptoms of filarial infection.

From the foregoing considerations it will be seen that filarial patients can be broadly classified into three types, (a) non-susceptible, (b) moderately susceptible, and (c) highly susceptible. The non-susceptible class show microfilariae on examination of blood and high eosinophilia, but do not show any obvious signs of the disease. These persons harbour the parasites

for several years without any apparent injury, as can be seen from the cases already reported, and are the main source for the spread of the infection. Dermal test shows uniformly positive but mild reactions in all of them.

In the second type (moderately susceptible) we find that there is lymphatic block with the result that no microfilariae are found in the blood. In Calcutta, many patients between the ages 18 and 22, including a number of Anglo-Indians, show these symptoms. The most common lesions seen in such patients are the static oedema and lymphatic varix of a mild degree in the arm, leg, or inguinal region. These lesions seem to remain stationary after a certain stage. The patients rarely give a history of having suffered from acute lymphangitis. They improve rapidly under treatment, remaining free from further infection. Eosinophilia is moderate and dermal tests give slightly more severe reactions.

The highly susceptible are those who develop obstruction quite early and remain susceptible for further infections. They suffer from periodical attacks of lymphangitis, each attack aggravating the lymphatic blockage and bringing about changes in the glands, lymphatic vessels and skin. Microfilariae are usually absent from the peripheral blood in these cases and eosinophils are practically normal. In these, dermal tests show acute reactions. Secondary infection plays an important rôle and severe pathological changes are quickly brought about. Advanced cases of elephantiasis of the limbs, genitals, and breast belong to this class.

Intensity of filarial infection

We shall now briefly discuss the various factors which influence the infection in a given area. Of these the more important are, (a) optimum atmospheric conditions, (b) the density of human population, and (c) the density of mosquito population.

By the term optimum atmospheric conditions we mean the most favourable temperature and humidity conditions for the transmission of filarial infection. It has been found that a temperature ranging between 80° to 90°F. and a relative humidity of above 60 are necessary for the normal development of the filarial embryos in the mosquito. It has also been observed that any deviation of the temperature and humidity affect adversely both the mosquito and the parasite undergoing metamorphosis in the mosquito. From a record of the daily average temperature and humidity observations in any given area we can mark out the period with the optimum temperature and humidity conditions necessary for the transmission of the infection. This period, which may be termed 'the effective period of infection', varies from place to place according to their physiography; it may be from April to October, as in Calcutta, or throughout the whole year, as in Cochin.

When there is crowding in an endemic area the chances of the number of carriers is great and thus the transmission becomes easier. In small villages owing to the thinness of population the disease is practically absent. An instance of village immunity may be mentioned here. The whole population of the village Osmanpur in Behar was examined for filarial infection, and, although in the adjacent town Purulia—which is only five miles from the village—one ward of about the size of Osmanpur showed a microfilaria rate of 7.5 per cent, no infection could be detected in the village. Surveys have been carried out in several villages, such as Khoira, Champati, Tulsipur, Bhaipur, Gangarampur, and Chagal, which are situated near endemic towns, Cuttack and Midnapur, and the results corroborate the above conclusion.

Infection is heaviest in towns and big densely populated villages, but is low in the cities. In the latter the good drainage and the piped water supply afford hardly any chances for mosquito breeding on a large scale, while in smaller towns and big villages conditions are more favourable for their breeding owing to the inefficient drainage and the uncovered water supply, chiefly from wells and tanks. In many of these places there is a pernicious system of building catch-pits for sullage and bath-water, and all these places afford excellent breeding grounds for mosquitoes.

We shall now see how these factors affect the incidence of filarial infection in some typical endemic areas.

high as in hyperendemic areas, but a satisfactory drainage system and good sanitary conditions keep down the number of *Culex* breeding-places in the city to a comparatively low figure. Furthermore the heavy rainfall during the months July to September tend to wash out the breeding-places and the mosquito population is exceptionally low. With the onset of the cold weather the mosquitoes increase in number but the most favourable period for transmission has now passed. It is seen therefore that the synchronization between the periods of transmission and mosquito breeding is reduced to the three months, April to June, and hence the comparatively low microfilaria rate of the city (9.1 per cent).

The incidence of filarial disease in Calcutta is 5.3 per cent, in spite of the microfilaria rate being only 9.1 per cent. These figures show a proportionately higher rate because of the fact that a large number of persons with filarial diseases come to Calcutta for treatment and are included in our statistics. For the same reasons, it is not possible to discuss the type of filarial lesions in relation to the microfilaria rate as one finds all types common.

Cochin.—This town is situated on the sea on the northern end of a long narrow peninsula, separated from the mainland by a backwater. It is very densely populated and has a climate which is hot and moist all the year round. Rainfall is heavy, chiefly received during the south-west monsoon. The following table shows the average monthly temperature, rainfall, and humidity observations at Cochin :

Monthly and annual normals, Cochin

Month	TEMPERATURE		Humidity at 8 hours	Rainfall	Number of rainy days
	Maximum	Minimum			
January	89.3	71.8	73.0	0.78	1.0
February	90.2	74.0	75.0	0.90	1.5
March	91.4	77.2	77.0	1.96	2.7
April	91.6	78.4	77.0	5.00	6.3
May	89.7	77.5	81.0	11.65	12.7
June	85.3	74.8	87.0	29.11	24.4
July	83.8	74.0	88.0	23.35	23.6
August	84.1	74.4	86.0	12.25	18.5
September	84.9	74.5	85.0	9.28	14.2
October	86.6	74.7	84.0	13.22	14.3
November	87.7	74.4	80.0	6.24	8.2
December	88.7	72.8	74.0	1.69	2.5
NUMBER OF YEARS ON WHICH THE DATA IS BASED.	33	33	22	51	51

Calcutta.—The effective period of infection for Calcutta is about seven months, April to October. Considering the crowding in the city and a fairly long period of transmission, the microfilaria rate might be expected to be as

It is seen that there is very little variation in the mean temperature and the high humidity during the whole year. Cochin therefore affords the very best climatic conditions for transmission of filarial infection.

There are open drains and ponds, in which coir is steeped, scattered all over the place, so that with the moderate temperature and humidity the conditions are particularly favourable for the breeding of *Culex fatigans*, practically all the year round. The effective period of infection for Cochin appears to be practically throughout the year and the microfilaria rate is above 20 per cent. Here the age incidence for filarial diseases is 8 to 10 years on account of the heavy infection. The filariae very rarely reach maturity in the main abdominal lymphatics, so that hydrocele, chylocele and chyluria are not usually observed as the obstruction of the distal lymphatics (i.e., the inguinal or epitrochlear) occurs very early in life. The superficial lymphatics are first involved and here the elephantoid conditions of the legs, arms, breast, etc., are seen as the most common clinical manifestation of filariasis.

As regards the relation between the period of infection and the microfilaria rate for Cuttack, Puri and Allahabad reference may be made to our previous paper (Aeton and Rao, 1930).

Relation between the intensity of infection and types of filarial diseases

In this same paper (Aeton and Rao, 1930) it was shown that there is intimate connection between the intensity of infections and the types of lesions produced. In hyperendemic areas the blockage is at the most distal set of glands and therefore the lesions are chiefly elephantiasis of the limbs. In areas of moderate endemicity the blockage occurs higher up and thus all types of filarial diseases are common. In areas of low endemicity the parasite is able to reach the juxta-aortic region and cause partial obstruction giving rise to varix and chyluria. No elephantiasis is seen in these areas.

(b) DUE TO SECONDARY INFECTION

We may now consider the pathological conditions produced by the secondary organisms. In a large percentage of infected individuals as the filarial parasites prepare the nidus the secondary infection plays an important rôle in the causation of lymphangitis, complete lymphatic obstruction, and rapid pathological changes in the tissues and skin. The most common organisms met with in these lesions are the streptococci and *Staphylococcus albus* and *aureus*.

Streptococci bring about acute attacks of lymphangitis, cellulitis or periadenitis producing elephantiasis, as in elephantiasis nostra. The organisms are usually derived from some focus, either external or internal, and can sometimes be isolated from the source as well as from the acute lesion. The mechanism by which they appear in the local areas has already been described in a previous paper (1929). Buxton (1928) suggests that the acute attacks of lymphangitis may be classified as centrifugal

or centripetal, according to the direction in which the inflammation spreads. This may be a guide to the source of the secondary infection. The various clinical diseases produced by these cocci in filarial patients are filarial colic, endemic funiculitis, abscess, cellulitis and general septicæmia. All these are of an acute and virulent nature. Death in filarial colic is usually the result of acute septicæmia and toxæmia, and in endemic funiculitis it is due to generalized peritonitis. In all these infections the fever is high, 103°—105°F., with a rapid pulse and a marked leucocytosis.

The chief clinical manifestations due to staphylococci are periadenitis, lymphangitis and abscess. The tissue reaction produced by these organisms may be distinguished from purely filarial infection by the nature of the exudate and the results of the culture. In the filarial infection they may undergo caseation and softening, and the pus is sterile. The fever is very slight and the leucocytosis is moderate.

Microscopical anatomy

We will now describe the various pathological changes that take place in the lymphatic glands, vessels and the skin in filarial infections, due to the parasite itself and to the secondary infection.

(a) *Changes in the lymphatic glands and vessels*

The filarial larva escaping from the proboscis of the mosquito enters the human skin, travels along the afferent lymphatics and enters the lymphatic gland. It reaches the medulla of the gland through the space between the trabeculae and the lymphoid nodules of the cortex. The dense reticular tissue of the medulla renders the passage of the larva through it difficult. Sometimes the larva is held up and destroyed by the endothelial cell granulation tissue. Giant cells are formed near the dead worms. The granulation tissue becomes vascularized by the formation of new blood vessels and is gradually converted into fibrous tissue, the process resulting in a scar in the medulla of the gland.

When a large number of filarial larvæ pass through a gland, the whole gland increases in size and in a short time is converted into a mass of eosinophil granulation tissue. As the lymph channels are obstructed by the granulation tissue, lymph can no longer percolate through the gland and the filarial larvæ also cannot pass through it. The afferent vessels are blocked, the lymphatic pressure rises and the vessels below dilate, particularly those of the hilum of the distal lymphatic gland. A complete description is given in the paper on 'Kataphylaxia' (Aeton and Rao, 1929).

Stages of elephantiasis

In describing the pathological changes in elephantiasis, it will be convenient to divide them into three stages, the first stage being

static œdema due to the effect of filarial toxin on the tissue permeability, the second lymph stasis with the formation of blubbery mass, and the final pachydermia stage due to the secondary infection of the skin added to the above.

Static œdema

When there is lymphatic blockage the toxins are confined mostly to the affected limb and are dammed back by the obstruction. The toxin possibly brings about an increase in the permeability of the tissue cells in the affected limb and causes static œdema which is aggravated by posture as in standing. In Calcutta, one finds this type most commonly in individuals between the ages of 18 to 22 years. Our records of the filariasis clinic show a surprisingly large number of Anglo-Indian girls, mostly typists, telephone operators and nurses under this head returned as 'lymphangitis—afebrile'. Ankles, feet and legs are chiefly affected; the affection is usually one-sided. The swelling reaches its maximum towards evening, clearing almost completely by rest overnight; the œdema pits on pressure, and the skin is otherwise normal; the attacks of swelling tend to recur periodically; the inguinal or axillary glands are very slightly enlarged and tender, and the main lymphatic vessel is thickened. These patients complain that periodically a small lump, the size of a pea, appears along the course of the main lymphatic, travels downwards gradually, and then disappears. This small lump is an aberrant migrating parasite which irritates the tissues, causes induration and sometimes forms a permanent cyst-like swelling in the legs or arms. The dermal tests are positive in every one of these patients tested. The microfilaria rate in this stage is fairly high and eosinophils range from 300 to 500 per c.mm. All these cases come from the hyperendemic areas of the city.

Second stage—Blubbery tissue

The œdema increases till it becomes more or less permanent. The subcutaneous tissue absorbs lymph and forms what is known as the 'blubbery mass'. When such a mass is cut out it is found to consist chiefly of lymph and white fibres. During this stage the limb has a smooth, glistening appearance, and pits on pressure. Lymphangitis recurs periodically in the affected limb and every attack aggravates the œdema and fibrosis. There is usually a tendency to the formation of abscesses, either along the main lymphatic vessel or in the devitalized tissue of the limb. As in the case of lymphangitis during this stage the abscess may be due to helminthic, or to secondary infection. The lymphatic obstruction is now almost complete, so that the filarial worms cannot proceed further along the vessel and aberrant migration takes place. Fugitive swellings and lymph-cysts appear in the limb. The microfilaria rate and eosinophilia are very low. A number of x-ray photographs have been taken of the

extremities and pelvic region in such cases. Figure 4 shows an opaque area in the inguinal region indicating calcified worms in a case of elephantiasis.

Fig. 4.—Skiagram showing opaque area of calcified worms in the left inguinal region in a case of elephantiasis of the left leg.

The pathological changes in the glands may be briefly described. The irritation of the glands, the destruction of the immature parasites by the reticulo-endothelial tissue and the gradual replacement of lymphoid tissue by fibrous tissue result in the hypertrophy of the gland; in hyperendemic areas the epitrochlear and inguinal glands are most commonly involved. On account of the short period of infection such conditions are rarely seen in areas of moderate or low endemicity. As the source of irritation is not continued for a sufficiently long period in these places the glands which are affected show enlargement only for a short period and then shrink down in the absence of irritation. When the hypertrophied gland is cut into it shows a fibrous mass with very little lymphoid tissue. Generally such glands do not contain parasites. The worms mature below the hypertrophied gland and the embryos which cannot reach the blood are destroyed in the tissues, thus aggravating the fibrosis. This leads to the third stage described below.

Third stage—Pachydermia

While in the first two stages the changes in the tissues are chiefly the result of filarial toxin and lymph stasis the third stage is brought about by the addition of secondary infection of the skin (epiblastic kataphylaxia). The defence mechanism of the surface layer or epidermis is gradually being impaired as the elephantiasis of the part is increasing in size. As the lymph

cannot be properly drained away from the surface areas, owing to the blockage of the terminal villous lymphatics in the papillae and owing to inflammatory changes in the junctional vessels in the region of the subpapillary plexus, it accumulates and percolates upwards to the prickle cells layer producing hypertrophy of the papillae. At the same time the keratinization of the horny layer is interfered with, so that the mechanical protection afforded by this layer is partially or completely lost. On the upper aspect of the foot and instep, and in the scrotal skin, groups of these terminal lymphatics may be involved in this obstructive inflammatory lymphangitis, so that the epidermis is thrown into large papillomatous growths and the dilated terminal lymphatics are seen giving rise to the so-called lymphatic cysts of the skin. Deep fissures form in the papillomatous area, owing to movements of the limb and the rigidity of the tissues of the corium, and the tissues are very prone to attack by secondary septic infections from the surface. Secondary streptococcal and staphylococcal infections under such conditions more usually come from foci situated on the skin surface.

Diagnosis of elephantiasis of filarial origin

Considerable difficulty is often experienced in distinguishing diseases such as dermatolysis, from elephantiasis of filarial origin. The former also cause swelling of the extremities and thus resemble true elephantiasis outwardly. The important points of diagnosis of elephantiasis of filarial origin are (1) a knowledge of the distribution of filarial infection and (2) history of the patient which were discussed in a previous publication (Acton and Rao, 1931). In doubtful cases a microscopic examination of the sections of the tissue will reveal the true nature of the lesion, for example in fibromatosis the changes are essentially a hypertrophy of the skin; these can be easily distinguished from the changes in elephantiasis.

Summary and conclusions

(1) The early history of elephantiasis and its differentiation from a group of diseases showing similar signs such as leprosy and Madura foot is traced. It is shown that cases of dermatolysis, hypopituitarism, elephantiasis nostra, etc., are often mistaken even at the present time for elephantiasis of filarial origin. Some of the common fallacies, for instance, looking for microfilariae in cases of elephantiasis and pitting on pressure as a diagnostic feature, are mentioned.

(2) Apparently-healthy persons may harbour filarial infection for a long time without showing any signs or symptoms. A few histories of infected persons who have been under close examination for about ten years are recorded. Filarial infection produces a low-grade pathogenic toxin, as is evidenced by the fact that in early stages of the infection when microfilariae are present in the blood there is eosinophilia.

Allergic symptoms appear according to individual susceptibility.

(3) Static oedema is the first stage of elephantiasis brought about by the filarial toxin affecting the tissue permeability.

(4) Various factors, such as density of mosquito and human population, and climatic conditions, which influence the prevalence of filarial infection and disease are discussed. The sites of blockage and the time of development of elephantiasis depend upon the intensity of the infection in a particular area. A few typical endemic areas which have been surveyed thoroughly are given as illustrating various degrees of filarial endemicity. In Cochin, where the optimum conditions prevail for the breeding of mosquitoes, the infection is heaviest and therefore the type of filarial disease common is elephantiasis of the extremities. In Calcutta, as a result of better sanitation and drainage the period of mosquito breeding is limited and thus the microfilaria rate is low, whereas the filarial-disease rate is high on account of the large number of imported cases.

(5) The pathological conditions produced by the secondary infections are described in detail.

(6) The various stages of pathological changes in the lymphatic system and the skin are mentioned.

(7) After every attack of lymphangitis the swelling increases. Types of adenitis and periadenitis in hyperendemic areas and in areas of low endemicity are given in detail. The eosinophil count is comparatively low. At this stage the lymphatic blockage is nearly complete, and the stagnant lymph soaking the subcutaneous tissue forms the blubber; errant migration takes place with the formation of fugitive swellings, lymph-cysts, etc. Worms die and get calcified; an x-ray photograph showing the calcified area is reproduced.

(8) The growth of the pachydermia stage is shown. The lymphatic obstruction is complete and therefore microfilariae are not present in the peripheral circulation. Worms die and form abscesses along the lymphatic channels. The toxin, and the pressure of stagnant lymph with the changes due to secondary infection, both from within and from outside (epiblastic katablaxia), complete the formation of the final stage of elephantiasis.

(9) Several conditions of lymphatic obstruction which are not due to filariasis are known. Clinical mistakes are often made owing to the difficulty in the differentiation of true filarial elephantiasis from this.

TREATMENT OF CHRONIC INTESTINAL AMOEBIASIS WITH CARBARSONE

By R. N. CHOPRA, M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

B. SEN, B.Sc., M.B. (Cal.)

and

S. SEN, M.B., D.T.M.

(Department of Pharmacology, School of Tropical Medicine, Calcutta)

THE difficulty of curing chronic amoebiasis is well known to physicians practising in the tropics. An acute attack of amoebic dysentery even in the majority of cases be successfully relieved by proper treatment, but eradication of the chronic intestinal infection with *Entamoeba histolytica* is a difficult matter. A large number of remedies are supposed to cure this condition, but most of these reduce the infection to a low level, so that the patient's own natural powers of resistance can keep in check the parasites which still remain in the body. Many of these patients become carriers.

Of the drugs used against amoebiasis emetine, although it is an excellent drug in acute amoebic colitis, often fails to cure the chronic condition. Halogenated oxyquinoline derivatives, such as yatren (loretin, quinoxyl), ehiniofon, vioform, etc., were highly spoken of but have proved disappointing. Some dye derivatives such as Rivanol (2-ethoxy-6:9 diamino acridine) and bismuth subnitrate have been tried with no better results. Acton and Chopra (1931 and 1932) tried the bismuthous iodide compound of the total alkaloids of *Holarrhena antidysenterica* in doses of 10 grains twice a day by the mouth for 10 to 20 consecutive days and they cured 73 per cent in a series of 78 cases. These results are considerably better than those obtained with any other drug tried by the senior author. The difficulties of obtaining satisfactory bark and of extraction of the alkaloids without producing decomposition, which renders them inert from the therapeutic point of view, are however considerable, and have been pointed out by these workers. The failures of kurehi alkaloids in the hands of Leake (1932) can thus be explained.

During recent years some organic compounds of arsenic have been tried in chronic amoebiasis. Stovarsol or acetarsone (3-acetyl-amino-4-hydroxy-phenyl-arsinic acid) was the first compound of this series which could be given by the mouth and it was tried in this condition, but the drug showed no curative action whatsoever in intestinal amoebiasis. Treparsol (3-formyl-amino-4-hydroxy-phenyl-arsinic acid) has also been tried, but with no better results. Leake (1932) suggested that carbarson (4-carbamino-phenyl-arsinic acid) had better amoebicidal properties than any of the other arsenicals. Reed and his co-workers (1932) tried it in a small series of cases and found it to be very effective and non-toxic.

Carbarson belongs to the original series of organic arsenicals prepared and tested by Ehrlich and Berthelm as long ago as 1909 and has the chemical formula $H_2O_3AsC_6H_4NHCONH_2$ being 4-carbamino-phenyl-arsinic acid. It is a white crystalline solid without odour or taste; it is stable in air and contains 28.85 per cent of arsenic when anhydrous. It is practically insoluble in water, but dissolves in alkaline aqueous solutions; it melts at 174°C. It is readily absorbed after oral administration and is excreted in the urine at about the same rate as stovarsol. Experimentally it is less toxic than stovarsol and has more powerful amoebicidal properties, its 'therapeutic index' being about eight times as favourable as stovarsol. As it contains a substituted amino-group in the para position to the arsenic atom, its liability to injure the optic tract should be borne in mind. No untoward symptoms were, however, observed after continued administration of the drug to laboratory animals in doses within the therapeutic range. Carbarson has been recently put on the market by Lilly & Co., of Indianapolis, U. S. A., and is sold in pulvules of 0.25 gramme ($3\frac{1}{4}$ grains) each.

After reading about the encouraging results obtained by Reed and his co-workers the senior author tried the drug in a series of patients in the wards of the Carmichael Hospital for Tropical Diseases. The patients were mostly suffering from chronic amoebiasis and the majority of them had had repeated attacks of dysentery. The drug was prescribed in doses of 0.25 gm. twice daily for 10 consecutive days in gelatine capsules by the mouth. The patients were kept on ordinary diet and, except a saline purgative whenever required to relieve constipation, no other drug was given.

The criterion of cure applied in this series was five or more negative examinations of the stools on different days after the cessation of all treatment. As has been pointed out in a previous paper, it is fully realized that it cannot be claimed that all such cases were really cured. However it is the best criterion that can be practically employed and from experience we know that five negative examinations indicate

in most cases a favourable prognosis if not a definite permanent cure. The difficulty of keeping the patient in the hospital when once the acute symptoms are relieved is very great, so for all practical purposes we had to accept this criterion. Whenever possible more examinations were made.

The records of 31 cases in which the drug was tried are given in a table which is self-explanatory. Out of 31 patients 23 (74.2 per cent) were cured, in 4 (12.9 per cent) the drug failed and in 4 (12.9 per cent) the result was indeterminate. As regards the indeterminate cases, although the patients left the hospital before the usual five examinations of the stools could be carried out, considerable improvement was noticed in their general condition after the treatment. A perusal of column 3 will show that the majority of the patients had suffered from the disease for long periods, and that many of them showed cystic forms of *E. histolytica* and had Charcot-Leyden crystals in their stools. The separate cure rates in vegetative and cystic forms of infections are given below and it will be seen that the drug is equally effective in either condition.

	Total	Cures	Indeterminate	Failures
Vegetative	11	8 (72.8%)	2 (18.2%)	1 (9%)
Cystic	20	15 (75%)	2 (10%)	3 (15%)

The proportion of probable cures to failures in this series is 5.75:1, as compared with 3.5:1 obtained by Knowles (1928) with emetine bismuthous iodide in a similar series of chronic cases.

Among the failures it is interesting to note that out of four cases only one had vegetative forms of *E. histolytica* and three had the cystic form. Some of the patients were infected with bacillary dysentery also, in addition to the amoebic infection. These were the most difficult to cure, but a course of autovaccine given either preceding or along with carbarsone treatment often brought about a cure. In case no. 27, carbarsone failed, but extractum kurchi liquidum with liver extract was effective. The usual course of carbarsone failed to cure case no. 7, but a cure was effected by a course of emetine bismuthous iodide 2 grains daily for 10 days.

It may also be noted here that in this series no untoward symptoms of any kind were produced either on the eyesight (due to the *para* position of the substituted amino-group), on the gastro-intestinal tract, or on any other organ or tissue of the body, by administration of the drug in doses of 0.25 gramme ($3\frac{1}{4}$ grains) twice daily for 10 days. Even those patients who were not cured improved in health generally, on account of the tonic and stimulating effects of arsenic on the system. Continuation of the drug for longer periods is now being tried in patients who have failed with the usual course of 10 days.

Summary and conclusion

1. Carbarsone (4-carbamino-phenyl-arsinic acid) belongs to the series of organic arsenicals originally produced by Ehrlich in 1909. It is a white crystalline solid containing 28.85 per cent of arsenic.

This compound has amoebicidal properties and is given in doses of 0.25 gm. ($3\frac{3}{4}$ grains) in gelatine capsules twice daily. In a series of 31 cases a ten-day course cured 23 patients (74.2 per cent), 4 (12.9 per cent) remained indeterminate, and 4 (12.9 per cent) remained uncured. The proportion of probable cures to failures in this series was 5.75:1, as compared with 3.5:1 obtained by Knowles in a similar series with emetine bismuth iodide, and 3.16:1 obtained by Aeton and Chopra with kurchi bismuthous iodide.

The drug produced no untoward effects in the doses administered, and is worthy of further trial in the treatment of chronic intestinal amoebiasis.

LETHAL PROPERTIES OF AQUEOUS EXTRACT OF YOUNG BAMBOO SHOOTS*

By A. D. STEWART

LIEUTENANT-COLONEL, I.M.S.

Director, All-India Institute of Hygiene and Public Health

and

V. N. MOORTHY, B.Sc., M.B. & B.S., D.P.H., D.T.M.

INTRODUCTION

It has been mentioned by Watt (1889) in his *Dictionary of Economic Products of India* that the different parts of the bamboo plant possess certain medicinal virtues. The tender leaves are commonly used in the form of a decoction to check diarrhoea in cattle. The expressed juice from the leaf bud is said to be an efficient emetic and an emmenagogue. The cold poultice made from the tender shoot is considered by villagers in guinea-worm-infected areas to be an efficacious application for the dislodgment of worms from ulcers. In a previous report on the subject (1932) it has been shown that the aqueous extract of the young bamboo shoot possesses, in addition, definite larvicidal and insecticidal properties. In this paper we have recorded the results of preliminary observations made to find out the active principles responsible for these different properties of bamboo shoots and also to determine the possible utility of these in larval and insect control measures.

EXPERIMENTAL OBSERVATIONS

(1) *Preparation of the extract.*—The outer coverings of the young bamboo shoots, about 1 to 1½ feet in height, were peeled off, till the soft inner core was reached. They were then cut into small pieces which were well pounded and the juice was expressed from them. This, after dilution with an equal quantity of water, was used in the following experiments.

(2) *Mosquitoes and mosquito larvæ.*—*A. stephensi* mosquitoes and their larvæ were used to test the toxic effect of the drug, since the preliminary observations showed that, of the different species of mosquito larvæ tested, these resisted the action of the drug for a relatively long time.

(3) *The species of bamboo used in the experiment.*—

- (i) *Dendrocalamus strictus*,
- (ii) *Bambusa affinis* (Munro), and
- (iii) bamboo shoots that are commonly sold in the market as a vegetable.

From the literature available, neither the chemical composition nor the medicinal properties of any of the species of bamboo mentioned appears to have been determined so far.

The only species of bamboo that has till now been experimented with appears to be *B. arundanacea*.

Toxic effects of an aqueous solution of bamboo shoot :—

1. *Guinea-worm embryos.*—These are killed by the extract in an average time of 12.5 minutes. The characteristic coiling and uncoiling movements of the embryos became gradually diminished and ultimately they were seen to die in a fully stretched condition and not in the fully coiled-up condition, as is usual when they are treated with chemicals, such as formalin or perchloride of mercury.

2. *Cyclops.*—The extract kills the cyclops in an average time of 10 minutes.

3. *Maggots of the house-fly.*—The extract kills the maggots in about 45 minutes.

4. *Adult flies.*—When a cotton-wool plug soaked in the extract was placed beneath a test-tube containing adult flies, they were seen to die in the course of 7 minutes.

5. *Adult mosquitoes.*—When a cotton-wool plug soaked in the extract was placed beneath a test-tube containing adult mosquitoes, they were seen to be killed in an average time of 3.5 minutes.

6. *Eggs of A. stephensi.*—250 c.cm. of water was taken and to this 2 c.cm. of the bamboo shoot extract was added. The eggs that were placed in this solution did not develop into larvæ while those placed in the control tube, containing 250 c.cm. of tap water only, developed into larvæ, pupæ, and finally into adult mosquitoes.

(A) Laboratory observations

(i) Undiluted extract, i.e., the expressed juice from the bamboo shoots without the addition of any water, kills the larvæ in an average time of 15 minutes. Under similar experimental conditions, a 5 per cent solution of potassium cyanide takes 22 minutes, and 1.2 per cent of hydrocyanic acid (B. P.) takes 19 minutes to kill the larvæ. The times taken to kill the larvæ by the bamboo-shoot extract, potassium cyanide solution and hydrocyanic acid solution respectively of different strengths are given in tabular form below.

(ii) One hundred c.cm. of the 50 per cent strength extract was taken in a Petri dish and the time taken to kill the larvæ by this was observed every day for a period of 25 days, at intervals of every 24 hours, the extract being kept exposed to the atmosphere during this period to facilitate the diffusion of hydrocyanic acid formed, into the air. The results of the observations have been expressed in the form of a graph. As is evident from the graph the toxic effect of the extract was at its maximum at the end of 24 hours on the second day of the experiment and then the extract became less and less toxic till the 6th day of the experiment when it took the maximum time of 4 hours and 18 minutes to kill the larvæ. As the

* Paper read before the Indian Science Congress, 1933.

TABLE

Table showing the lethal time for *A. stephensi* mosquito larvæ when treated with bamboo-shoot extract, 5 per cent KCN solution, and 1.9 per cent HCN solution of different strengths

Percentage concentration	TIME TAKEN IN MINUTES FOR LARVÆ TO DIE. AVERAGE OF 15 READINGS		
	Bamboo-shoot extract	5 per cent KCN	1.9 per cent HCN (B. P.)
100	15	21.9	19.5
66.6	15.5	22.2	21.5
50	17.2	25.1	23.2
33.3	26.2	28.7	30.2
25	33.6	29.5	32.5

GRAPH

Average time taken for 15 *A. stephensi* larvæ to die on different days of the experiment (in hours)

solution became more and more concentrated with the second toxic principle, on account of the evaporation of the fluid, its toxic effect on the mosquito larvæ also gradually became increased and was at its maximum again when the volume of the solution was reduced to nearly 10 c.cm. At this period on account of the deposition of heavy solid matter the fluid was

semi-jelly-like in consistency. It was once again diluted to its original volume of 100 c.cm. and the observations continued for another 15 days. This diluted fluid was still toxic to the mosquito larvæ, but it took nearly 24 hours for the larvæ to be killed. Unlike the extract on the first day of the experiment which had a definite toxic action on the adults, pupæ, larvæ, and eggs of the mosquitoes, this fluid was found to have relatively no effect on the pupæ. But it was noticed that the imagines emerging out of the pupæ usually died on the surface of the fluid. Eggs placed on this extract hatched out into larvæ, but these were immediately killed by the extract. Hence this fluid appears to be toxic only to the larvæ and imagines of the mosquito.

From the first to the fifth day of the experiment the extract gave a positive reaction to the following tests for hydrocyanic acid.

- I. Guignard's picrate paper tests (Ghosh, 1930).
- II. Copper acetate benzidine paper test (Sherrard, 1928).
- III. Prussian blue test (Allen, 1930).
- IV. Thiocyanate test (Allen, 1930).

On the 5th day of the experiment all the above-mentioned tests, except the copper-acetate-benzidine test, were negative and on the 6th day all the tests were negative. The extract remained acid to litmus throughout the course of the experiment.

These observations indicate that the toxic effect of the bamboo shoot is possibly due to :—

- (a) the free hydrocyanic acid liberated probably as the result of hydrolysis of one of its cyanogenetic glucosides effected by a specific enzyme,
- (b) another toxic principle either naturally present in the bamboo shoot or formed when the extract is kept exposed to the atmosphere for some days.

The latter conclusion is based on the fact that the toxic effect of the extract on the mosquito larvæ continued when the presence of hydrocyanic acid could not be detected in the extract by the most sensitive tests. This is further supported by the fact that, while it took 22 minutes and 19 minutes for the larvæ to be killed by 5 per cent potassium cyanide solution and 1.9 per cent of hydrocyanic acid solution respectively, it took only 15 minutes for the concentrated bamboo-shoot extract to kill the same species of mosquito larvæ under identically the same experimental conditions, though the percentage of available hydrocyanic acid in the species of bamboo shoots experimented with was not more than 0.6 per cent as determined by Liebig's (Allen, 1930) silver-nitrate method and calculated on the original sample. As is indicated in the graph, the toxic effect of the extract from the first to sixth day of the experiment therefore appears to be due to both hydrocyanic acid and another toxic

substance present in the extract and on subsequent days of the experiment it is due mainly to the second toxic principle, all the available hydrocyanic acid at this period having been hydrolysed and diffused into the atmosphere. As the extract became concentrated with this second toxic principle on account of slow evaporation of the fluid, its toxic effect on the mosquito larvæ also attained its maximum once again on the 12th day. When the solution was once again diluted to 100 c.cm. it still remained toxic to the mosquito larvæ but the time required to kill the larvæ in this dilution was about 24 hours, as contrasted with 15 minutes taken by the original extract on the second day of the experiment, when it contained, in addition, the maximum of hydrocyanic acid liberated.

(B) Field observations

The observations so far made are practically confined to the laboratory findings and till now only a few preliminary observations have been made in the field. When 15 ounces of the concentrated bamboo-shoot extract was added to a borrow-pit measuring about two feet in diameter and three feet in depth and containing a large number of mosquito larvæ, it was found that all the larvæ were killed in the course of about four hours. In addition it was of interest to see, on the next morning, six adult female mosquitoes and two gnats lying dead on the surface of the water. Possibly when these mosquitoes had gone near their breeding place to lay eggs as usual, they were killed by the hydrocyanic acid gas slowly liberated by the action of the specific enzyme on the cyanogenetic glucoside present in the bamboo shoot.

These cyanogenetic plants appear therefore to be a valuable source of hydrocyanic acid and the fundamental difference between the hydrocyanic acid produced by chemical means, as for example by treating an alkaline cyanide with a mineral acid, and that produced by the plant by the action of the specific enzyme on the cyanogenetic glucoside is that by the latter method, which we may call 'nature's method', the hydrocyanic acid is liberated slowly for a long time, about 6 days; and the amount liberated appears to be sufficient to exert a lethal action on the larvæ and adults of insects like mosquitoes, while in the former case, *e.g.*, in the case of 'cyanogas' and liquid hydrocyanic acid (B. P.) which was used as controls, the liberation of hydrocyanic acid and its lethal effect on the mosquito larvæ was noticed only for 4 or 5 hours, under similar experimental conditions.

CYANOGENESIS IN PLANTS

There is as yet no consensus of opinion on the physiological significance of cyanogenesis in plants. In the literature on the subject the following three main ideas as to the significance

of the production of hydrocyanic acid in plants have been traced :—

1. Hydrocyanic acid is an intermediate product in the synthesis of proteins.
2. Hydrocyanic acid is formed by the plant as a means of protection against insect pests.
3. Hydrocyanic acid formed is a waste product of no metabolic significance.

It is generally believed that the specific enzymes are situated in cells different from those in which the cyanogenetic glucosides are present. Whenever the plant cells are destroyed, as by insect pests or when they are crushed as by grinding them, the enzymes are brought in contact with the glucoside and, as the result of the hydrolysis of the glucosides thus effected by the enzymes, hydrocyanic acid is liberated and kills insect pests. In this connection it is of interest to note the opinion held by the famous plant biologist, Dr. Burek (Greshoff, 1906), that the trace of the hydrocyanic acid in the arum plant plays a very special part in the biological process as it gradually narcotizes and kills any insects which may have penetrated into the flower after they have performed their task of self-fertilization. Of significance in this connection also is Guignard's (Armstrong and Armstrong, 1931) observation that exposure of living plants to the action of anæsthetics, like chloroform, and also exposure to severe cold, brings about the interaction between the glucoside and the corresponding ferment. These conclusions are based on the experimental observations made by him on laurel leaves and other cyanophoric plants.

Whatever may be the significance of the presence of hydrocyanic acid in plants, with the few preliminary observations that have been made so far, this method of getting hydrocyanic acid by the hydrolytic action of specific enzymes on the cyanogenetic glucoside appears to be useful and specially suited for insect control measures. With properly-devised methods it may be possible to imitate nature's method of manufacturing hydrocyanic acid and use it for the control of insect pests of mankind, in the same manner as apparently the plant protects itself from its insect pests.

Summary

- (1) Aqueous extract of young bamboo shoots kills cyclops, mosquito adults and larvæ.
- (2) The toxic effect of the extract appears to be due to :—
 - (a) Free hydrocyanic acid liberated as the result of the hydrolysis, possibly of one of its cyanogenetic glucosides by a specific enzyme contained in it.
 - (b) Another toxic substance the nature of which is still under investigation.
- (3) The cyanophoric plants are a valuable source of hydrocyanic acid and with properly devised methods it may be possible to imitate this nature's method of manufacturing

hydrocyanic acid and to apply it in the field for insect control measures; the liberation of hydrocyanic acid by this method being slow as contrasted with chemical methods, the toxic effect therefore lasts for a longer period.

Our thanks are due to Mr. C. C. Calder and Mr. K. Biswas, of the Royal Botanical Gardens, Calcutta, for having kindly supplied us with the bamboo shoots, and also to Dr. Sudhamoy Ghosh, of the Calcutta School of Tropical Medicine, for the kind help given in the course of this work.

THE NON-TOXICITY OF PLASMOCHIN AND ATEBRIN

By W. B. McQUEEN, M.B., Ch.B. (Glasgow)
D.T.M. (Liverpool)

Beesakopie, Doorn Doorn P. O. and T. O., Upper Assam

IN 1931 I introduced in my practice the standard treatment for malaria suggested by Lieut.-Colonel Sinton (1930) in this journal. During that year my assistants and I treated 7,857 cases by one or other of the three courses recommended, including the plasmochin course, and gave to 4,049 children with enlarged spleens quino-plasmochin in *gur* twice weekly, as a gametocidal measure. All malaria cases were treated as in-patients. In 1932, owing to the length of time in hospital involved in the two-weeks and three-weeks treatments, we changed the treatment to the ten-day one suggested by Lieut.-Colonel Knowles (1931) also in this journal. During that year we treated 4,697 cases by this method, and gave to 1,038 children plasmochin simplex for its gametocidal effect, choosing all the children in one line on each garden instead of children with enlarged spleens in all lines.

During these two years no toxic signs appeared in the children treated 'in the field', and in less than half a dozen cases in hospital had we to lessen the dosage of plasmochin, or suspend

treatment till causes of intestinal irritation had been attended to.

It was not until atebtrin had proved its worth very conclusively in other places, that I was able to obtain it for extensive use; but previously I used it in two cases of blackwater fever.

The first was a Punjabi mistri's wife who was seven months pregnant. Partly owing to the pregnancy, she had not followed instructions, and had treated her occasional fever in the way commonly done in the Punjab and Rajputana. Then one morning she woke up about 3 A.M. and found that her urine was black. When seen she complained of fever, vomiting, intense thirst, and pain in the abdomen and back. Her temperature was 101.8°F., and there were dyspnoea, tympanites, tenderness over the liver and spleen, and jaundice. At intervals she was semi-conscious and passed urine involuntarily. What urine could be collected contained blood cell debris. She was treated for one day in the classical way, suggested in *Manson's Tropical Diseases*, ninth edition. Next day she was put on atebtrin, and that night she miscarried, but the placenta was retained. The assistant medical officer removed the placenta manually under far from ideal conditions—the patient was in a house with bamboo mud-plastered walls—taking what precautions were possible. Next day the condition had improved considerably, the jaundice being much less intense. On the following day urine was obtained free from lochia, and was clear and practically free of albumin. Septicæmia followed and was treated concurrently with the atebtrin and plasmochin course. Recovery was uneventful. The patient was advised to seek a district less malarious and left in good health after some months, having had no fever meanwhile.

The second case was in a Bengali clerk's wife, who had had blackwater fever in 1928 and again in 1930. The risk from the third attack, which occurred during November 1932, being considerable, we used atebtrin followed by plasmochin. Her recovery was uneventful, and she has been free from fever since.

I may add that we did not adopt atebtrin in the treatment of blackwater fever because we had had disappointing results with other methods; on the contrary, we have always had excellent results with the 'classical' method, referred to above.

I have now treated five Europeans, and with my assistants, many Indians with atebtrin and plasmochin, and the only trouble we have experienced has been in one European, who on the eighth day of treatment—namely three days after the course of atebtrin was finished—complained of pain in the epigastrium. It was not severe enough to prevent him expressing a wish to attend a parade of the Assam Valley Light Horse that afternoon.

Conclusion

Both plasmochin and atebtrin can be used with absolute safety 'in the field', provided reasonable care is exercised in their administration.

RICE INFECTION AND EPIDEMIC DROPSY*

By SARASI LAL SARKAR, M.A., L.M.S.

Late Civil Surgeon, Noakhali

and

B. M. GUPTA

District Health Officer, Noakhali

At Raipur, a village situated in the north-western extremity of the district of Noakhali on the banks of the river Dacathia, Dr. U. C. Nath has built, equipped and staffed a large surgical hospital for the accommodation of his patients. Dr. Nath was in the habit of buying in small quantities the rice necessary for consumption in his family. He varied this practice in February 1930, when a boat containing a large supply of *Balam*† rice, came from Barisal district for sale in his village, Raipur, and from this boat Dr. Nath bought 25 maunds of rice, while a friend, Babu C. R. C., bought 25 maunds and a rice merchant in the local bazar bought the remainder, which was about 25 maunds, for sale in the locality.

There were no cases of epidemic dropsy amongst any people in the village of Raipur, several of whom undoubtedly used the rice from this boat; there were no cases of epidemic dropsy in the house of Babu C. R. C., the members of whose family gradually consumed the rice stocked in his house; but there was a severe outbreak of epidemic dropsy in the house of Dr. Nath, with one death, about eight months from the date of buying the stock of rice. The family of Dr. Nath was the only family that suffered from the epidemic in the populous village of Raipur.

Although all three bought from the same boat, different methods of storing the rice were employed; Dr. Nath stored the rice in a *dol* which is a very big bamboo basket capable of holding several maunds of rice. This kind of basket is prepared by villagers for storing food grains like rice. He smeared the outside of this basket with cow-dung. On the top of the rice stored in this *dol* was put about a seer of lime to protect the stored rice from insects. The *dol* was put upon a wooden platform to protect it from damp and moisture.

After filling the *dol* with the quantity of rice bought from the boat, it was found that there was a balance which could not be accommodated in the *dol*. This remaining rice was stored in a number of gunny bags and in a *matki*, or big earthen vessel, which was kept in the kitchen, to obtain the supply of rice necessary for preparing the daily meal. This *matki* was kept on the floor of the kitchen which was damp. As the stock of rice within the *matki* was exhausted, it was refilled from the stock in the *dol*.

When Dr. Nath bought the 25 maunds of Barisal rice he already had a stock of country rice bought from the bazar; this had to be consumed before he began to use the new rice. It took some time to consume the old stock of rice which was in the *matki* and gunny bags, so that the rice in the *dol* remained undisturbed for about two or three months. However, the exact time of this cannot be definitely ascertained. When using the rice from the *dol*, the upper layer which was mixed with lime was thrown away.

Babu C. R. C. stocked his 25 maunds of rice as follows:—He had in his house several big earthen vessels which were 30 years old. These were soaked in mustard oil some years ago and preserved their oil-soaked appearance at the time when the rice was stored in them. These vessels were kept on bricks. The balance was stored in few gunny bags and this rice was first used up. During the rainy season, i.e., one day in the month of July, Babu C. R. C. exposed his stock of rice for about two hours in the sun, taking it out of the earthen vessels and spreading it out in a thin layer.

The local merchant who bought rice from the boat stored it in a *gola*, which is a small closed circular room made with bamboos and placed on a bamboo platform, but this rice was rapidly used up and did not have long storage, as in the other two cases.

Now in the house of Dr. Nath, nothing remarkable happened for about 6 or 7 months, though all the members of the family used stored rice. At this time there were guests and relatives, who came to stay in the house and lived for two or three weeks and then went away. They were not affected.

Two Christian nurses attached to the hospital obtained cooked rice from Dr. Nath's kitchen, while they prepared other articles of their diet themselves. At the beginning of October 1930, they noticed that the cooked rice that came from Dr. Nath's kitchen was somewhat distasteful and therefore began to purchase their own independent supply of country rice for cooking. These two nurses were found to be suffering from slight cedema of feet, when examined, so they undoubtedly had a mild attack of epidemic dropsy.

About the middle of October, Dr. Nath, while performing a prolonged serious operation in the hospital, found himself so exhausted that he had to sit down for a while and rest during his operation. He afterwards noticed the swollen condition of his feet, but he did not suspect epidemic dropsy. A few days later, Dr. Nath's mother-in-law with two adult female relatives, and three children, one of whom was only a year old, came to the house. At this time the last portion of the stocked rice which was at the bottom of the *dol* was being consumed by the members of the family. Within about 10 days all the members of Dr. Nath's family manifested marked symptoms of

* Rearranged by the Editor.

† *Balam* rice is a parboiled highly-polished rice; it retains little or no pericarp.

epidemic dropsy. The new-comers, who had not been in the house more than 10 days, except the baby who was being breast fed, all became markedly affected like the rest of the family. About this time a guest came to the house and stayed about three weeks. He did not eat cooked rice, but took instead *luchis*, which is a food made from flour, along with other articles prepared in Dr. Nath's kitchen. He altogether escaped being affected with this disease.

Two servants of the house who occasionally took food from Dr. Nath's kitchen and often took food in their own houses were found to be suffering from slight oedema of their feet. Thus, besides the two Christian nurses and the two servants, five adult females, two daughters and one son, aged between 14 and 12, one child aged 3½ years, and Dr. Nath himself suffered from epidemic dropsy and as a result one of Dr. Nath's daughters died with the symptoms of difficulty of breathing and heart failure.

A quantity of rice was sent for examination and the following report was received:

'About 80 per cent of the rice grains were found to be spotted or wholly opaque and damaged, and floating on water-test. On microscopical examination with the low power, several of the rice grains were found to contain yellowish oval bodies, probably eggs of some insects infecting the rice. Bacteriological examination were made after careful external sterilization of rice. Cultures from them showed very numerous varieties of fungi and spore-forming micro-organisms. In some of the plates, there were very numerous micro-organisms with spores at the two extremities with a clear space in the middle. These micro-organisms were Gram negative'.

The study of an isolated occurrence of epidemic dropsy like the present one, though it

leads to no definite conclusion, suggests several points regarding the aetiology and pathology of epidemic dropsy for our consideration.

According to certain writers, the causal organism of epidemic dropsy possesses the characteristic of being changed from a saprophyte to a pathogenic organism by the change of its environmental conditions. The outbreak described in this paper tends to support the above view. For it will be seen that the consumption of the last portion of the rice stocked in the *dol* caused the outbreak not only amongst the members of the family, but also amongst the new-comers, who took the rice only for a short period.

Now if we accept the supposition that a pathogenic micro-organism has appeared in the last portion of the rice, which has caused the disease, it is difficult to explain how this particular micro-organism appeared only in this particular specimen of rice, but this difficulty can be overcome by the supposition that a saprophytic micro-organism in the rice has been changed into pathogenic micro-organism by environmental conditions such as dampness, want of light and air.

The most important practical lesson gained by the study of the epidemic appears to be, that the sunning of the rice, especially during the rainy season, is a good prophylactic against epidemic dropsy.

While epidemic dropsy was caused by preserving rice in a *dol* besmeared with cow-dung outside and kept in a damp room, it was not caused by another sample of the same variety of rice which was preserved in earthen vessels soaked previously in mustard oil. It is possible that mustard oil exerts some preventive action against the appearance of the micro-organism which causes epidemic dropsy. The matter is worth further investigation.

A Mirror of Hospital Practice

A FATAL CASE OF AMBULANT TYPHOID FEVER

By R. RAMANUJIAH, L.M.P.

Railway Dispensary, Mettupalaiyam

THE following case is of considerable interest on account of the rarity with which such cases are encountered:

A thin, wiry man, aged about 27 years, an employee in the local railway workshop, reported sick on the 13th January, 1933, with a temperature of 103°F., and a history that the attack was preceded by rigors. Malaria was suspected and cinchona febrifuge grs. 10, three times a day, was prescribed and continued for three days.

On the 4th day, the fever subsided to 99°F. in the morning and rose to 102.4°F. in the evening. The patient began passing ten to twenty loose greenish motions a day. He did not feel ill even when the temperature was 102.4°F. His only complaint was of the diarrhoea. The tongue was very clean and continued

to be so till the end. The pulse was in keeping with the temperature and showed no dicrotism. The patient got up to pass his stools. However, enteric fever was suspected, dietetic restrictions were enforced and the patient was warned about the danger of getting out of bed. Bismuth was given for two days, but there was no improvement in the diarrhoea. An acid chlorodyne mixture was prescribed for two more days with the same result.

On 21st January, 1933, the patient was very much exhausted by the diarrhoea. The fever was of a low hectic type, 99°F. in the morning, 100°F. to 102°F. in the evening.

On 23rd January, 1933, he was given bismuth salicylas grs. 90 and tincture opii m. 30 in three ounces of water. The diarrhoea improved very much and the patient felt much better. He was very hungry and consequently neglected the dietetic restrictions and took two tumblers of thick rice *conjee* for the night.

At 12 o'clock that night, he passed a large quantity of blood and slough per rectum. Before 7 A.M. on 24th January, 1933, he had passed half a dozen such motions,

when I was called to see him. The man was very much exhausted, the extremities were cold, there was a gurgling noise in the abdomen, and the right lower quadrant was slightly tender to touch and dull to percussion. He was treated with an ice-bag on the abdomen, ice to suck, morphia hypodermically and calcium lactate in grs. 30 doses by mouth. The hæmorrhage was controlled.

On 25th January, 1933, he passed small dark shiny motions. At 2 p.m. the temperature was 104°F. (reactionary fever?)—the highest recorded during the disease. Morphia gr. $\frac{1}{2}$ hypodermically and calcium lactate by mouth was repeated and a sponge bath was given. The patient could not be confined to bed. He insisted on getting out of bed to go to stool.

On 26th January, 1933, at 8 p.m. he started passing frequent and alarming quantities of blood and slough. In spite of treatment, the man collapsed and died within four hours.

On account of the course of the disease we must assume that the patient continued his work for about ten days after the onset of his illness before reporting sick.

I wish to express my thanks to Dr. J. K. Manson, M.B., Ch.B., my District Medical Officer, for getting me permission to publish these notes.

ACUTE MASSIVE ATELECTATIC COLLAPSE OF THE LUNGS

By S. R. PRALL, M.D. (Cantab.)

MAJOR, I.M.S.

*Acting Civil Surgeon, and Superintendent,
B. J. Medical School, Poona*

The following case appears to be worthy of record:—

Mr. N., at. 56, was admitted into hospital on 24th January, 1933, complaining of fever with rigors for the last four days. About three weeks ago the patient had a sharp attack of influenza from which he had not wholly recovered when he got the present attack of fever. He is subject to intermittent attacks of malaria. On admission his temperature was 99.8°F., pulse was 86, and respiration rate 22 per minute. Tongue was clean, lungs clear, and no abnormal physical signs were discoverable. No malarial parasites were seen in the blood. Urine was normal, except for a trace of albumen.

Progress.—Patient complained of some pain in the liver region but on examination there was no tenderness on pressure. The stools were examined on 27th January and nothing abnormal was discovered. It was decided to try the effect of emetine as the fever still continued. For five days following the emetine treatment the temperature remained normal but rose again on the sixth and subsequent days so it was discontinued. Pain and tenderness in the liver region continued and a total leucocyte count showed 25,600 on 6th February. Up to this time, although patient had a slight cough, the sputum was scanty, and no physical signs of bronchitis could be discovered.

On 7th February the routine examination revealed entirely fresh signs. There was dyspnoea with rapid onset, and a sense of oppression rather than pain in the right side of the chest. The distress was marked and the patient seemed acutely ill. The areas of the right upper and middle lobes of the lung were dull on

percussion whereas the base was hyper-resonant—the note being suggestive of a pneumothorax. The liver dulness was pushed down and the diaphragmatic movement on

Fig. 1

Fig. 2.

the right side was definitely impaired. On examination of the heart it was found difficult to map out the area of cardiac dulness but it was definitely made out that

the heart was drawn over to the right side to a marked degree. On auscultation tubular breathing with bronchophony was heard over the areas dull to percussion, while the crepitant râle of pneumonia was conspicuously absent.

The x-ray findings were as follows:—The left lung appeared normal and the left side of the diaphragm moved well. There was a dense shadow in the areas of the upper and middle lobes of the right lung and fixation of the right side of the diaphragm. The base of the right lung appeared normal. The heart was drawn well over to the right side so that the shadow only just extended to the left of the sternum.

The patient was instructed to lie on the unaffected side, and possibly also aided by the movement in carrying him to the x-ray room, improvement in his condition commenced. The physical signs in the chest, on his return from the x-ray room, had changed and moist râles were heard all over the affected areas; the position of the heart was unchanged.

The general condition of the patient continued to improve, the fever ceased and there was no respiratory distress. Sputum, which was now expectorated easily, was muco-purulent and contained no tubercle bacilli.

His improvement was closely followed by use of the x-rays. On 11th February right side of diaphragm moved slightly on respiration and the upper lobe of right lung was clearing. Heart was still over to the right side. On 13th February the range of movement of diaphragm has increased and there is now only a shadow in area of middle lobe. Upper lobe is quite clear. Position of heart unchanged. On 15th February further improvement in diaphragmatic movement. Shadow in middle lobe has diminished. Heart's position not changed. On 21st February lung is now clear and the heart has almost recovered its normal position.

Fig. 3.

Commentary.—The case exhibits the characteristic features of acute massive atelectatic collapse of the lungs. The physical signs, although suggestive of either consolidation or effusion, are distinguishable from both of these

conditions, when it is remembered that the essential part of the diagnosis is the displacement of the heart towards the side of the lesion. The only other condition in which this occurs is fibrosis of the lungs, but when the condition has developed acutely it is always an expression of collapse. A feature of this displacement is the slow return to normal after the lung has become aerated again. In clinical medicine, collapse may be an associate of most of the acute thoracic affections or an accident following many surgical operations, particularly those upon the abdomen. Any tendency to weakness or shallowness of the respiratory activities predisposes to collapse though there is evidence to show that there will always be found actual obstruction of some form or other in the bronchi or bronchioles. The present case is of interest in illustrating the importance of keeping in mind the possible occurrence of collapse in connection with a latent affection of the air passages and lungs.

As regards the direct treatment of the condition, some authorities maintain that exploratory puncture, though no fluid may be obtained, has a dramatic effect in clearing the lung. In the present case, however, turning the patient on the unaffected side was efficacious and resulted in rapid improvement.

I am indebted to Captain N. H. Kulkarni, D.M.R.E. (Cantab.), Radiologist at the Sassoon Hospitals, for the x-ray and radioscopy reports, which were of great assistance.

A CASE OF DIAPHYSIAL ACLASIS

By P. N. RAY, B.A., M.B., F.R.C.S. (Eng.)

(Surgeon, Carmichael Medical College Hospitals, and Additional Surgeon, General Hospital, Howrah)

THIS rare condition is known under a multiplicity of names, e.g., multiple cartilaginous exostoses, hereditary multiple exostoses, etc.

The patient, a Hindu male child aged 12, complained of swelling around both the knees and the left ankle with hard nodules, which were slowly increasing in size. No pain or functional disability was complained of. The condition was first noticed about two years ago.

History of past illness.—No history of rickets. The patient suffered from what was described as a severe sprain of the left ankle, nearly two years ago.

Family history.—A careful enquiry was made with regard to family history. No other brothers or sisters were affected. There was no history of such a disease in the father's line, two generations back. But no such definite information could be obtained with regard to the maternal line.

On examination.—The patient was under-nourished and was below the average height and weight for his age. Multiple exostoses were present in different parts of his skeleton, about the existence of some of which he was unaware. The principal sites were around the knee joints and the upper ends of the humerus and the fibula. Smaller ones were present over the radius, ulna and the ribs. The bones of the face and the skull were not involved. Phalanges were also free from exostoses. Deformity was marked, especially around the knees, but there was very little curvature of the long bones. The proportion between the trunk and the lower extremities was normal. There was hardly any

deformity of the wrists. The patient was quite an intelligent boy.

Radiographic appearance.—Practically the whole skeleton was first examined under the screen and

Fig. 1.—Skiagram of both knees, showing the characteristic bony changes.

Fig. 2.—Skiagram of the left ankle, showing an exostosis, causing pressure atrophy of the shaft of the fibula.

skiagrams were taken of the parts, where marked changes were noticed.

Proliferative changes.—These are well marked on either side of the epiphyseal line, especially around the knee joint. The lower end of the femur and the upper end of the tibia are converted into cylinders of bone. The epiphyses are also much enlarged and distorted, but no definite outgrowths are present in these regions. But the head of the fibula is characterized by the presence of a distinct epiphyseal outgrowth, which, on the right side, is almost cystic in appearance. Near the diaphyseal ends of the femur and tibia, pointed stalactite-like outgrowths are present (figure 1).

In the diaphysis of most of the long bones, multiple exostoses or osteo-chondromata are present and they show various stages of ossification. Some of these have not passed beyond the stage of chondromata. But apart from the presence of these outgrowths, no great deformity or curvature is noticeable. A fairly large cancellous osteoma is situated near the lower end of the left tibia, causing pressure atrophy of the shaft of the fibula (figure 2).

The patient was advised to report from time to time, and at once on the appearance of pain or functional disability, in the absence of which no operative treatment was advised. This case was first seen by me a year ago and I have seen him several times since.

In conclusion, I have to thank the radiological department of the Carmichael Medical College Hospitals for the excellent skiagraphy.

A PENETRATING WOUND OF THE ABDOMEN*

By P. B. MUKERJEE, L.M.P.

Tajpur, Darbhanga

A HINDU boy aged about 10 was brought to this dispensary from a village four miles off with a tear in the abdomen, through which part of the intestines were protruding.

The history was that on the morning of the same day, he was gored by a bull. The protruding intestines were wrapped in dirty cloths and he was brought at once to the dispensary.

There was a wound about three inches in length and one and a half inches in breadth running obliquely upwards across the left side of the abdomen and terminating at the costal margin; through this a portion of the descending colon and omentum were prolapsed. There was a considerable amount of dirt adhering to the protruding organs. Under chloroform anaesthesia the soiled intestine was cleaned as far as possible with warm normal saline and returned to the abdomen. The wound was stitched in layers, silk being used for the deeper sutures, the skin was closed with horse-hair sutures and a dressing of iodine applied.

Three days later the boy was removed to his home and I saw him nine days afterwards when I found the superficial part of the wound suppurating and gaping widely but the deeper layers appeared to have united satisfactorily. The few stitches that remained in place were removed, the wound was cleaned, packed with iodized gauze and bandaged.

From this time on the wound made satisfactory progress and healed completely in a short time.

THE PRESENT METHODS OF THE KING INSTITUTE IN THE PRODUCTION OF VACCINE LYMPH

By H. H. KING

LIEUTENANT-COLONEL, I.M.S.

W. J. WEBSTER, M.C.

MAJOR, I.M.S.

K. P. MENON, L.R.C.P. & S.

and

KHAN SAHIB MAHAMED OOMAR SAHEB

(From the King Institute, Guindy, Madras)

Introduction

It is often forgotten that the first generally successful method of preventive immunization was not Pasteur's anti-rabic method but Jenner's vaccination against small-pox. Here in India, where small-pox among the unprotected is all too common, the importance of vaccination is readily recognized. But, while this is so, most medical men are ignorant of the methods used in obtaining a potent lymph; some have even thought that the virus is obtained from small-pox cases. Accordingly, we thought it would be of interest to outline briefly the chief details of our routine methods elaborated in the course of 30 years' experience as an institute. Further, such an account might be useful and suggestive to those working with other viruses. Here, we are not concerned with history; those who are interested should consult *Vaccination and Small-pox in British India* by S. P. James.

Seed lymph

The strain of lymph now used was obtained in 1920 from the Belgaum Vaccine Lymph Depot. This and the strains used by other vaccine institutes in India appear to have been originally obtained from England; importation began in 1802.

Lymph for the inoculation of calves is either ordinary lymph, or lymph obtained from final-passaged cow-calves by a process first of selection and then of passage through other animals. Selection is simply taking lymph for seed only from calves that show the best results. For many years this was the only method used in most vaccine institutes until a striking advance was made by Nijland in Java, who found that the potency (capacity to 'take') was considerably enhanced by using seed lymph that had passed first through a rabbit and then through a buffalo-calf, Nijland's cycle is thus cow-calf—rabbit—buffalo-calf—cow-calf. Until recently this has been the cycle used, but now it has been modified by the addition of a second buffalo-calf to seed cycle. This (King's) modification has still further increased not only the potency but

also the yield of lymph per calf, which has gone up from a previous average of 23 grammes to an average of 30 grammes.

Production of stock lymph

All calves are supplied by contractors who make their purchases in rural areas of the Salem District of the Madras Presidency where apparently bovine tuberculosis does not occur. As a test of this, in 1932, about 200 tuberculin tests were carried out on calves by the double intracutaneous method; all were negative. Supplies of calves are stopped when reports of foot and mouth disease are received from that area. The calves are inspected on arrival at the institute by a veterinary officer and after 14 days' quarantine, they are, if thoroughly healthy, released from quarantine and taken into 'reserve' for use as required. It may be said that illness among these calves is not common. Occasional slight mange or coccidiosis is treated; if severe, the calves are rejected. Usually, the general appearance of the calves improves markedly as a result of good feeding and careful grooming.

On the day prior to operation, the selected calves are shaved on the belly and inner side of the near hind thigh. They are kept overnight in the waiting sheds where special attention is devoted to cleanliness. A clean apron is used to cover the shaved part and this is changed if it happens to become soiled.

When the calves are put on the operation tables, their bellies are washed with soap and warm water, then thoroughly rinsed with warm water, and finally flushed with sterile water and dried with towels. The seed lymph diluted to 1:5 with 50 per cent glycerine is then applied by means of a scalpel. The edge of the scalpel is dipped into the seed lymph and is then used to make an incision about 3 or 4 inches long. The incision is as deep as possible without drawing blood. Perfect incisions are only made after considerable practice. Subsequent incisions prolong the line across the shaved area but stop short half an inch from the hairy margin. At the completion of each line, the back of the scalpel is drawn along the whole line to ensure contact of the lymph with the depths of the incision. Eventually, a series of incisions about $\frac{3}{4}$ inch apart is completed, the appearance of the belly on completion being indicated in figure 1. The total incisions equal about 250 linear inches on the average, but this varies considerably with the size of the calf. The calves remain under the punkah for a quarter of an hour and are then taken to clean sheds where they are prevented from lying down for some hours. After this, clean aprons are used to protect the area of operation. They are inspected after 104 hours and in a small proportion, about 5 per cent, the lesions are judged to be already so mature that the lymph should be removed. The majority are, however, at their best after 120 hours. All lesions are

carefully washed and rinsed and then soaked with a sterile cloth dipped in sterile water to encourage softening. After 5 minutes or more,

Fig. 1.

when the lesions are dry, the results are carefully scrutinized, and each calf's lesions are classified according to the appearance. A perfect result is given 4 marks, but this is very rare; figure 2 shows an almost perfect result.

Fig. 2.

The majority earn 2 to 3 marks. Less than $1\frac{1}{2}$ marks leads to rejection while lesions with a value of over 3 marks may be selected for seed. This classification cannot be made without long experience of the work. The lymph is then removed by means of a Volkman's spoon. The operator keeps the line of vesiculation on the stretch with his left thumb and draws the spoon firmly along the whole line, removing all lymph and scab. The contents of the spoon are then scraped off into a bottle which bears a distinguishing number corresponding to the serial number of the calf. This process is repeated until all the lymph is removed when the contents of the bottle are weighed and noted. The yield of six calves, normally those vaccinated with the same strain, is pooled to form a 'cup', i.e., a quantity, roughly 150 grammes suitable for pulping,

storing and testing. Lymph from rejected calves and from specially-marked areas of other calves, where lesions have been damaged, etc., is put in a special coloured bottle, treated with permanganate solution and thrown away.

The removal of the lymph being completed, our original practice was to smear the area with a mixture of vaseline and eucalyptus oil and then to dust with an astringent powder. Recently, this practice has been modified and improved upon by Webster who uses 1 per cent potassium permanganate or Eupad, either of which successfully lessens secondary vesiculation by destroying most of the virus; healing is thus much accelerated. Next day, the calves are handed over to the contractor for disposal. The calves are not killed and so post-mortem examinations are not done. The amount of glycerine (50 per cent) to be added to each 'cup' to give a $1:2\frac{1}{2}$ dilution of the lymph having been calculated, this is gradually added, first in a mortar and later in the course of passage through the pulping machines. Three separate pulping machines of increasing fineness are used and a homogeneous mixture of glycerinated lymph results. This is stored in bottles at a temperature at or just below freezing point—storage at temperatures several degrees below freezing point is quite unnecessary.

Bacteriological tests

Initial test.—A sample of each 'cup' is taken as soon as it is pulped and glycerine solution is added to give a $1:5$ mixture, which is then examined bacteriologically. To estimate the total organisms present, 10 cubic millimetres of the sample is added to 10 cubic centimetres of saline and mixed. Ten cubic millimetres of this is added to melted agar, mixed and poured into a Petri dish. After 48 hours at 37°C . the total number of colonies is counted. About 30 cubic millimetres of the sample is added to (a) litmus milk, (b) broth under paraffin, and (c) cooked meat medium. All these are incubated anaerobically for 48 hours. If any show growth, smears are examined for the presence of spores. The broth culture from three samples (whether showing growth or not) is pooled and 2 cubic centimetres of the mixture is injected intraperitoneally into a guinea-pig. If the animal dies, each broth culture is again tested separately. Subculture from the broth is also made on to agar and, after incubation, a search is made for streptococci. A 'cup' would be rejected if pathogenic spore-bearers, haemolytic streptococci or any pathogenic organisms, other than staphylococci and non-haemolytic streptococci, were found in the cultures, or if guinea-pig inoculation showed the presence of harmful organisms.

No vaccine lymph is issued until it has been stored (below or near freezing point) for at least a month to allow adequate reduction of extraneous organisms under the action of glycerine.

After that time, it is tested for potency and purity and released for general issue as required.

Final purity test

This is a total count of colonies and it is carried out exactly as in the early test. It shows that the extraneous organisms have been greatly reduced in number and in practice it is quite usual to find the lymph sterile at this stage. In Great Britain under the Therapeutic Substances Act, the standard is 'less than 5,000 organisms per cubic centimetre'.

Potency test.—This is carried out on calves. Six 'cups' are tested on each calf and to diminish the chance of working with an unsatisfactory calf (e.g., a calf resistant to vaccinia) the experiment is duplicated, i.e., two calves are used for each set of six 'cups'. The shaved belly of each test calf is marked out into six areas and each area is further divided into two or three, depending on the number of dilutions to be tested. Samples from each of the six 'cups' are diluted to 1/500, and 1/1,500. About five one-inch incisions are made for each dilution. The results are read after 120 hours. A perfect result shows complete vesiculation in all dilutions and in practice the usual result is 'almost complete vesiculation in the 1/1,500 dilution' and complete vesiculation in the others. This calf test was first introduced by Cunningham and then the dilution used was only 1 in 500. The potency having increased, higher dilutions have had to be used for differentiation as seen from figure 3 where the lower half is 1 in 500

Fig. 3.

and the upper half 1 in 1,500, the vesiculation with the latter is almost continuous.

Less than two vesicles per linear inch in the 1/500 dilution used to lead to rejection. This standard is now applied to the 1/1,500 dilution. In Great Britain, a lymph dilution of 1 in 1,000 must produce the characteristic lesion when applied to the scarified skin of a rabbit or guinea-pig.

Field test

A sample from each 'cup' at this stage is issued for the vaccination of children in the

local Saidapet Range. This provides evidence close at hand of the efficacy and harmlessness of the 'cup' in the event of unsatisfactory results or complaints from other districts and thus gives us a very satisfactory control.

When the 'cup' has been passed for issue, it is filled into tubes as required. One cubic centimetre represents 30 human doses with four insertions each. The dilution is 1 in 7 of the original calf lymph—1 in 5 in the hot weather. The present filling arrangement as devised by King is that lymph is delivered into tubes from a large-barrelled syringe the plunger of which is controlled by a micrometer screw so graduated that one full turn of the stem delivers one-half cubic centimetre of lymph from the nozzle. The tube is then corked and the corked end dipped in melted paraffin. The label of the tube has a distinctive colour depending on the number of doses. Each tube is wrapped in tow and tubes are packed in cardboard boxes according to demands. The contents of each box in tubes and doses is shown on the address label.

The seed

As mentioned above, seed is selected from calves showing particularly good vesiculation. About 5 grammes are removed from the best areas of the selected lesions. This is diluted to 1 in 2½ with 50 per cent glycerine and stored in the cold until required. When it is to be rejuvenated, generally within a few days, it is further diluted to 1 in 5 and a dozen drops are spread on the shaved back of a rabbit. The area is then thoroughly scarified with a matchstick. Seventy-two hours later, the rabbit lymph is removed with a blunt metal spatula after the usual washing and softening, and further material is removed after rubbing a few drops of glycerine solution on the area. The rabbits used are observed for a month before and after operation. Any suspicious illness leads to rejection of the seed, especially anything suggesting the possibility of encephalitis.

The rabbit lymph is diluted to 1 in 5 with glycerine solution and is used at once to vaccinate buffalo-calves. Two first-series buffalo-calves are used for each two strains of rabbit lymph. Thus the first buffalo is vaccinated with one rabbit strain on the anterior part of the belly and with another strain on the posterior part, while in the second buffalo the positions are reversed. The skin is tougher than in cow-calves and a sharp scalpel is used. The incisions are 2 to 3 inches long and about 1½ inches apart, and 30 to 40 incisions are made for each rabbit lymph. The results on the buffaloes are read after 104 hours and lymph is taken from one or both animals according to the appearance within 120 hours of vaccination. The two strains are kept separate, but the yield from the same strain on the two calves may be pooled if both are satisfactory. The lymph is removed, ground and diluted with glycerine

solution and stored as usual. The passage through two second-series buffaloes is carried out in exactly the same way and the yield from these is used as seed to vaccinate calves for the production of stock lymph as required. There is usually an interval of about one week between each of the last few passages.

Notes

1. The slow bactericidal action of the glycerine is aided by the addition of 0.1 per cent clove oil which apparently does not now seriously affect the virus. So experiments are again being done to see whether this can be made the normal practice without real damage to the virus. With the less potent lymph previously used, it was found that clove oil damaged the virus, but it is hoped that this will no longer be the case.

2. While routine production is confined to the cooler months in Madras—September to February inclusive—it has been found by experience that seed lymph stored during the hot weather is not so satisfactory as fresh seed lymph obtained by regular passages during this period.

3. Vaccine lymph rapidly loses its potency at a high temperature. It is, therefore, recommended that supplies from the institute exposed to ordinary temperatures of the Madras Presidency should not be used more than four days after receipt. In Great Britain, under the Therapeutic Substances Regulation, 1927, a statement has to be printed on the label to the effect that unless the lymph is stored at a temperature under 10°C. (50°F.), the potency cannot be guaranteed for more than 7 days.

4. The animals are comfortably housed as seen from figure 4. The area vaccinated is a

Fig. 4.

comparatively small one so the animals suffer very little from the process. The practice of vaccinating along the flanks as well as the ventrum, as is done in some places, is to be deprecated.

CEYLON HEALTH UNITS*

By W. P. JACOBS, M.D., D.P.H.

Advisory Health Officer to the Department of Medical and Sanitary Services, Ceylon

Introduction

No unusual difficulty is now experienced in planning a suitable public health organization for a municipality. Numerous models are available for study throughout the world. The question is only one of meeting the budget demands.

In rural sections the situation is different. The means of raising revenue are often unsatisfactory; the distances to be traversed are great; communications are frequently bad; and the general educational, financial and sanitary levels are low. On the other hand, rural areas contain the greatest number of people and as they are the main sources of wealth of the world, their sanitary environmental conditions should be promoted.

The establishment of health units in rural and semi-rural areas in Ceylon and India has aroused considerable interest among health workers and the general public. In this article the organization of an official unit in Ceylon is described.

Health units

The health unit scheme presupposes that fundamental public health principles are universally applicable. Local financial and other conditions should be taken into consideration, and the procedures which are followed should be based on common sense and on a recognition of what is useful, reasonable and practicable. The object is to bring to rural areas the benefits of health protection which are now enjoyed by large towns and cities. This end is accomplished by dividing rural areas into suitable districts and introducing therein small but completely trained bodies of workers who remain permanently in the delimited area and undertake all public health problems. Their activities embrace health education, general sanitation, collection, tabulation and study of vital and morbidity statistics, control of preventable endemic and epidemic diseases, vaccination and preventive inoculation, maternity and infant welfare work, school health work, and adult hygiene.

More than 600 of these organizations are now functioning in all parts of the world, namely, Ceylon, India, the Straits Settlements, Siam, China, the Philippines, the South Pacific Islands, Europe, the West Indies, South America, Central America, Mexico, the United States, and Canada.

Ceylon

The island of Ceylon is 20 miles south-east of India. It contains 25,322 square miles and,

* The activities reported in this paper were carried out under the auspices of the Government of Ceylon and the International Health Division of the Rockefeller Foundation.

according to the 1931 census, has a population of 5,312,548. It lies wholly within the tropics (6-10 north latitude) and embraces a wide coastal plain and a narrow band of foothills surrounding a central mountainous area. The predominating race—Sinhalese—are Buddhist in religion; the remaining one and one-half millions are Hindus, Mohammedans and Christians. The principal preventable diseases are malaria, infection by hookworm and other intestinal parasites, enteric fever, dysentery, leprosy, plague and tuberculosis. Cholera and smallpox rarely occur.

In normal times, the country is prosperous and progressive. Large estates of tea, coconut and rubber are the principal sources of wealth.

Ceylon has been in contact with western countries since the 16th century and is well advanced in education. Vernacular and English secondary schools are located throughout the Island, and good colleges are found in Colombo, Kandy and other large towns.

A medical college gives full preparation for local practice, but those entering the public health service must offer, in addition, public health qualifications obtained abroad.

The Director of Medical and Sanitary Services is in charge of all curative and preventive work. Distributed throughout the country are 112 hospitals (9,436 beds) and 603 dispensaries, all staffed by government-employed doctors and apothecaries. There are comparatively few private practitioners, but their number is increasing.

The public health branch has 28 medical officers of health. For the most part, the country is divided into districts each under a medical officer of health whose activities consist of the promotion of sanitation and the control of communicable diseases with the aid of sanitary inspectors. A district medical officer with a large area and a small staff of inspectors can only touch the fringe of the necessary public health work, and in Ceylon this type of work, still necessary under existing conditions in many provinces, is now considered to give inadequate results and is being replaced by health units, as rapidly as facilities permit.

Health unit work, adjusted to local needs, was commenced in Ceylon in 1926. In December 1932, eight health units were in operation embracing 856 square miles and containing 440,000 people. The following data in regard to this work are taken in part from the 1931 report of the Department of Medical and Sanitary Services:

Work and personnel.—The type of work carried out has continued as originally planned and the personnel employed is as follows:—8 medical officers of health, 1 medical officer, 51 sanitary inspectors, 12 public health nurses, 48 midwives, 9 clerks, 8 peons, and 11 orderlies and labourers. A hookworm dispenser was attached to each of the units for varying periods during the latter part of the year. The eighth unit was organized too late in 1931 for its figures to be included.

Births and birth rates.—The births in seven of the

units amounted to 12,702 giving a birth rate of 36.7; as compared with 33.1, the rate for the 35 principal towns of the Island. (Statistical collection in health units is more comparable to the collection in the 35 towns than to the collection in the Island as a whole.)

Deaths and death rates.—The deaths in seven of the units total 7,668 giving a crude death rate of 22.1, as compared with 29.6, the rate for the 35 principal towns of the Island.

Infant mortality.—A total of 1,807 infant deaths occurred in seven of the units, giving an infant mortality rate of 142, as compared with 187 for the 35 principal towns of the Island.

Maternal mortality.—There was a total of 229 deaths among mothers at childbirth in seven of the units, giving a maternal mortality rate of 18, as compared with 31.3 for the 35 principal towns of the Island.

Still-births.—Figures for still-births are available only for the urban areas of the different health units. There has been a total of 86 still-births, giving a still-birth rate of 54, as compared with 73.4, the figure for the 35 principal towns of the Island.

Maternity, infant and pre-school hygiene.—The number of health centres has increased from 22 in 1930 to 35 in 1931. The number of child-welfare clinics held is 1,276 as compared with 843 in 1930. At these centres 489 expectant mothers paid 1,259 visits, as against 136 expectant mothers and 561 visits in 1930; 1,313 infants paid 9,917 visits, as against 892 infants and 6,142 visits in 1930; 1,360 pre-school children paid 8,476 visits, as against 874 pre-school children and 6,193 visits in 1930.

Forty-eight trained midwives attached to the health units made 53,129 ante-natal visits to 8,538 expectant mothers at the rate of 5.8 visits per mother and attended at the delivery of 4,985 mothers, paying them 34,582 post-partum visits at the rate of 6.9 visits per confined case. Eleven public health nurses visited 10,450 homes paying a total of 15,810 visits.

Communicable diseases.—1,746 cases of communicable diseases were reported and 1,727 were investigated; 2,911 doses of anti-typhoid vaccine were administered; 10,670 vaccinations against smallpox were done in six of the units by health unit inspectors. Hookworm treatments amounting to 17,689 persons were carried out in all the units.

School hygiene.—There are 313 schools with a school population of 54,473; of this number 5,669 were medically examined; 4,027, or 70 per cent, were found to be defective with a total of 8,376 defects, or 2.1 defects per defective child; 1,647, or 19 per cent of the defects found, were corrected.

Latrine construction.—135 public latrines in all the units received 8,235 inspections. 172 defects were found and 8 public latrines were newly built during the year.

Latrine construction was carried out in all the units; 71,924 dwellings are provided with 29,886 latrines at the rate of one latrine to 2.4 houses. During the year 1,853 new latrines were constructed, as against 1,713 in 1930, and 1,239 were altered to sanitary type, as against 994 in 1930.

313 schools are provided with 255 latrines, i.e., one latrine to 1.2 schools. During the year 19 schools that were without latrines were provided with them.

Public health education.—Public health education has been carried out by means of 152 lantern lectures, 145 lectures without lantern, 16 cinema lectures, 684 school talks, 1,324 village talks, 215 clinic talks; 4 health and baby weeks reaching an estimated population of 152,000, or 34 per cent of the health unit population; 325 conferences with health unit staffs have been held and training in health habits introduced in 14 schools in the different units.

In addition to these detailed activities, 20,101 houses were surveyed; 1,594 consultations and 123 adult examinations were given; 133 public wells received 2,616 inspections; 197 bakeries, 1,041 tea and coffee boutiques, 194 eating houses, 11 aerated-water manufactories, 66 meat stalls, 83 fish stalls, 174 vegetable stalls, 83 dairies, 234 laundries, 170 cattle sheds, 3 soap manufactories and

94 brick and lime kilns received 80,220 inspections revealing 35,666 defects of which 46 per cent were remedied; 8,099 cattle were inspected and 7,852 passed; 4,381 goats inspected and 4,367 passed; 172 samples of milk were examined, and meat, fish and vegetables were seized as unfit for human consumption on 31 occasions.

This enumeration gives an idea of the scope of work performed in health units and indicates the all-inclusive programme which is carried out. The Director of Medical and Sanitary Services closes this part of the report with these remarks: 'This type of work is now being accepted by the people as the line along which health work in the Island should progress'.

The first health unit, Kalutara Totamune, is used by the department as a training station, and as a consequence has a larger staff and a larger budget. Medical officers of health, public health nurses, midwives and sanitary inspectors now attempt no field work until they have spent an allotted period of time at specified tasks in the health unit organization. Twenty-two public health officials from nine countries have visited the Kalutara Totamune and other units to study the methods in use in Ceylon.

Map.—In order to visualize the complete problem the Island was divided into 63 health unit areas which are indicated by differential colouring on a map. To simplify statistical collection, the existing revenue boundaries were utilized.

Selection of first area.—Considerable care was taken in selecting the first demonstration area. The points which were kept in mind were as follows:—

(1) The leading people should earnestly desire the work. Unless this frame of mind is present or secured, it would hardly be worth while making the attempt. This is probably the most important factor in the whole field of selection.

(2) It is essential that the early co-operation of officials should be secured.

(3) It should be located at a district administrative centre. The work is thus recognized as having received the definite approval of government and as a consequence this establishes it as a government effort.

(4) It should be at or near the seat of the central government in order that the work can be given supervision by higher officers and guided along proper channels, and in order that it can be frequently inspected and visited by officials, and easily accessible as a demonstration to visitors and others who are interested.

(5) It is self-evident that the area should contain the usual health problems of the country. There should be a reasonable amount of prosperity and educational advancement.

(6) It should contain town, village and rural populations. If the first unit embraces all groups, the work can be applied in any part of the country.

(7) It should contain the desired number of people. If groups are too small, the overhead expense is great and the numerical data collected are insufficient for proper statistical analysis.

(8) It should be well connected with roads. A medical officer of health spends most of his time in the field in contact with the people of his area. It should be possible for him to reach them easily and promptly.

(9) It should contain a hospital which will supply medical and surgical treatment for the sick who are found during the survey, and assist in correcting defective children, and in complications of pregnancy.

(10) All organized towns and villages in the area should contribute financially up to their capacity. If

necessary, they should pass laws to enable the medical officer of health to carry out the required work.

(11) The first area should be developed with the idea of utilizing it as a training centre for health unit workers. It is economical to have a training station in the country as it avoids the expense of sending officers away for training and enables them to study the home problems in the home environment.

With one exception, these requirements were met in Ceylon with the selection in 1926 of the revenue area known as the Kalutara Totamune.

It is obvious that in the selection of succeeding areas all the points enumerated above need not be stressed, but a unit should not be established in any community which does not evince an active interest in the subject and show a desire to co-operate in every way. Responsible people of the locality can give the necessary assurances.

It is probably unwise to attempt to interest villagers in serious health work in those sections where there is not a fair degree of prosperity. If a villager has to struggle for his daily bread, and to be content with scanty and mean clothes and primitive shelter, it is not reasonable to expect him to listen to health propaganda of any sort. After his poverty is somewhat reduced, his food and clothing reasonably assured, his fields productive and his house respectable, he will have time and inclination to consider other matters. Consequently remote or backward districts should first receive other fundamental attention.

Area of work

Experience in Ceylon indicates that a population of about 80,000 can be successfully handled by the health unit staff, although a smaller population is preferred in the beginning. The first Ceylon area included representative groups living in small towns and villages and on estates. The people included doctors, lawyers, teachers, priests, government servants, planters, shop-keepers, fishermen, cultivators of village gardens and estate labourers.

Value of hospital and dispensary

The dividing line between curative medicine and public health is not clearly defined. It is true that the functions in certain instances are widely separated and in others closely joined. The tendency is towards a more intimate alliance in health unit work. Hospitals are of assistance in maternity and infancy work and in correcting defects found at school medical inspections. This is feasible in Ceylon inasmuch as the curative work and public health work are under a single direction.

Staff.—The health unit organization consists of a permanent staff of trained workers as follows:—Medical officer of health, public health nurses, midwives, sanitary inspectors, clerk and peon. These are full-time workers with recognized qualifications acceptable to and approved by government. The use of government staff is advantageous as the officers can be transferred readily if circumstances require. As in all types of work the quality of accomplishment depends upon the character of the staff selected.

These workers undertake all the public health activities in the area, but specialists from the central office may be called on to make surveys and give advice. All health units are supervised by a senior staff officer.

Medical officer of health.—In addition to the professional qualifications already mentioned, a medical officer of health should be a competent person with field experience and thoroughly interested in his subject. He directs the health work done in his area and inspects

the work of his subordinate staff with sufficient frequency to keep in touch with all phases of each activity. He is the administrative officer of the organization and uses a motor car for travel.

Public health nurse.—The nurse is frequently referred to as the most important member of the staff. It is certain that in relation to maternal and child-welfare work she is an essential cog in the machine. She must be interested in her work, tactful, sympathetic but forceful in carrying out her duties. She should be well known to the people and able to enter the homes without hindrance. By gaining the confidence of the mothers, she will secure their co-operation and become acquainted with the actual situation in the homes.

Public health nurses should be self-reliant, healthy, not elderly in the beginning, and able to do outdoor work at all seasons. Unlike the hospital nurse who works exclusively indoors, the public health nurse does home visiting, gives home demonstrations, and attends pre-natal and post-natal clinics. She supervises the work of the midwives, and after ten days takes charge of the mother and child, and devotes her energies to keeping them well by home visits and by urging attendance at weekly clinics till the child reaches school age. Her activities include also smallpox vaccination, home demonstrations in the care of minor ailments and assistance in school health work. She lives in the district assigned to her and travels by motor car, rickshaw or hackery (bull and wagon). Young married women as well as single women have been found to be satisfactory public health nurses. Under the present methods a Ceylon public health nurse deals with a population of 8,000 to 10,000, but this number will be altered as the work develops and as more nurses become available.

Ceylon public health nurses are trained 4 years (in general nursing 3 years, in midwifery 6 months, and in public health nursing 6 months).

Midwives.—Like all the staff, the midwives are approved by government after 6 months of successful training. In health unit work they are placed under the immediate supervision of the public health nurse. They locate expectant mothers, and take care of them prior to, during confinement and for ten days thereafter.

One midwife is expected to deal with a population of 4,000 within a radius of 3 miles and to do at least 12 confinements a month. They live in the assigned area and travel on foot. It is desirable that the midwife be married and that the entire family stay with her in the area. The health unit midwife is gradually replacing the untrained woman.

Sanitary inspectors.—Inspectors are trained by government medical officers of health for a period of 6 months. Their work includes control of communicable diseases, inspections of water supplies, houses, dairies, markets, hotels and restaurants, tea kiosks, bakeries, and housing and the promotion of latrine construction. In addition they are trained to do smallpox vaccinations and to give mass hookworm and malaria treatment. Each inspector is required to become well known in his area and to gain the co-operation of the people. As with other members of the staff he works on a programme approved by the medical officer of health, and his activities are frequently visited. An inspector is able to deal with a population of 8,000. He lives in his assigned territory and uses a bicycle for travel.

Office.—An office with necessary clerical staff is located in the area. It frequently happens that a government or municipal building can be secured for an office without pay. Rented buildings are used for the central office, but any other building is supplied by the local population as a part of their co-operation.

The clerk is in government clerical service. He is selected for his ability to type and to deal with correspondence and with forms and reports which reach the office from the field.

Laboratory.—A room at each health unit office is equipped for making simple laboratory examinations of stools, blood and urine. The work is done by the medical officer of health or a trained assistant. Material

requiring more complicated procedure is sent to the central laboratory in Colombo for examination.

Cost.—The cost of the work varies with the scale of pay in operation in a country and of the number of staff employed. The cost should be divided between the central government and the local authority in accordance with arrangements agreed upon in advance. Activities paid for by the local authority are confined to the limits of the area controlled by the local authority.

It is important that the central government, as well as the local authority, contribute towards the work. Very few rural communities in any part of the world will be able to support a competent health programme from the village or town finances. In Ceylon local organized communities are asked to contribute the necessary number of sanitary inspectors and midwives and to continue to pay the cost of scavenging and conservancy. The central government provides the rest and correlates the activities in all units.

All members of the staff whether paid by the local or central government are placed under the control of the medical officer of health of the health unit.

In 1931 the cost to government of operating 7 units was Rs. 2,12,381, or 2.2 per cent of the department's expenditure. The expenditure of the local authorities is not recorded as these expenditures would have occurred if there had been no health unit. A budget for a typical area is appended.

Procedure.—After the area was selected and the staff chosen and located, the following procedure was found suitable.

Educational.—(a) An inaugural public lecture was given by a prominent official. This point should be decided in accordance with local conditions. The publicity gained in a formal public opening is often of great assistance in getting satisfactorily started, but a quiet beginning has advantages.

(b) A series of subsequent lectures were given at various points in the area by the medical officer of health containing detailed information about procedure and describing methods of co-operation.

(c) Steps were taken by the medical officer of health for the formation by the people of local societies to assist in carrying out the work.

(d) A systematic effort was made to enlist the active support of prominent persons including leaders in all phases of local endeavour.

Survey.—A detailed house-to-house survey of the area is made on a special form to secure an accurate understanding of the health needs. The survey is all-inclusive and enables the staff to become acquainted with the people and the area, to find out the general sanitary conditions of the environment and to learn the prevalent diseases.

Activities.—After the survey is finished, the data are analysed and the public health problems so revealed are taken up in the order of their importance.

The entire staff work on a definite pre-arranged programme, prepared in accordance with the problems to be met, the seasons, and the general local conditions. In part their work consists of the following activities:—

Health education by means of press articles, pamphlets, lectures with lanterns and cinemas, village and school talks, individual talks by nurses and sanitary inspectors and exhibits. A small library is developed.

Securing co-operation by enlisting the interest of individuals and organizations and obtaining financial help from individuals; by utilizing existing societies and, if there are none, the organizing of social service and other co-operating bodies.

Promoting sanitation through the development, by experiment and practice, of suitable methods of general sanitation, particularly the control of soil pollution by the use of latrines, inspection of food, markets, eating

places and houses, and the establishment of water supplies and sewage disposal plants.

Controlling communicable diseases by the prevention of cholera, smallpox, chicken-pox, measles, plague, malaria, enteric fever, dysentery, hookworm disease and filariasis; by organizing special treatment campaigns against hookworm, malaria, yaws and leprosy; and collecting morbidity statistics.

Vital statistics, collection, tabulation and study.

Personal hygiene, which is promoted by child-welfare clinics at various centres, home visiting by public health nurses, midwifery service, and medical inspection of school children and correction of defects.

Weekly conferences.—A weekly conference attended by all members of the field staff and presided over by the medical officer of health is held every Saturday morning in the health unit office. At that time each member of the field staff presents his own problems of the week which are discussed and decisions as to the procedures to be followed are arrived at. At this conference advance programmes for the following week are prepared. The conference is useful in maintaining interest by keeping members of the staff informed concerning all phases of the work and is a regular activity in all health units.

Co-operation

Public health work done by compulsion has no sound foundation. A health unit should be able to carry out its work without being compelled to enter prosecutions. Resort to law is the final step. A conviction makes enemies and secures compliance only with the particular item under consideration.

To get lasting results the work must be placed on a co-operative basis which is the foundation of the health unit system. Co-operation is obtained by carefully explaining in lectures and personal conferences to those concerned the objects to be attained and the assistance which may be given in carrying out the programme. Types of co-operation are :

Community.—Social service organizations were formed in the totamune at Kalutara and at Beruwala to assist in promoting the child-welfare work. They continue to function in the original manner. Sub-committees were named for each health centre and a member attends the weekly clinics at the centre, arranges for the distribution of milk to those needing it, and conducts the sewing activity of the little-mother classes. The leagues are supported by private donations, monthly contributions and 'our-day' collections, and their activities are not a charge against the health unit budget. At Beruwala the local league furnishes a building as a centre for holding the weekly well-baby clinic.

Private.—Two public-spirited people rented and furnished two buildings for holding weekly well-baby clinics at two centres. Two other people donated land, building and furniture for operating one clinic. One superintendent provided a good building on his estate on a yearly nominal rent, and one person provided a pump for a public well in a village.

Municipal.—When the health unit includes a self-governing town or village, it is necessary to have an understanding with the local officers. A conference is arranged and after the details are explained, the local authority learns that it loses no power over its employees, but gains considerable help without additional expense. The following rules have been adopted and have proved satisfactory. The local authority agreed to :

(a) Entrust all the municipal health work to the medical officer of health of the health unit.

(b) Pass the necessary regulations and bye-laws to enable the medical officer of health to carry on his work in a satisfactory manner.

(c) Contribute the salary and allowances for the required number of approved sanitary inspectors and midwives.

Objections

In spite of the success attained by health unit work, criticisms of health units have been made by some well-informed and responsible people, but for the most part by those who know nothing of the system. Some of the criticisms are that health units are :—

(a) *A western idea and not suited to the conditions or the people of the east*.—After careful consideration, this does not seem to be a real objection as many western ideas have already been adopted in the east. Furthermore, the statement has been made that in ancient village governments, sanitation was an important item of the administration. If that is true, the health unit only attempts to restore these early usages.

In 1933 this objection lacks force as there are 8 units in operation in Ceylon and several in India, Burma, Siam, the Straits Settlements, Java, the Philippine Islands and other eastern countries. In all these units the adaptation to local conditions were kept in mind and put into practice.

(b) *Too costly*.—It is true that the cost is greater than district work in a similar area, but even so the *per capita* expenditure is less than that usually recognized for carrying out efficient public health work. Although more is paid out, more is received for the outlay. A man must pay more for a silk suit than for a cotton suit as he gets a better article which gives longer and better service. The health unit prefers to accentuate quality of work.

A proposal to introduce health units into the entire area of any state or any country at one time has not been made and is not feasible for numerous reasons. Trained staff is not available; many areas are not suitable for any type of efficient health service; and the people are frequently not prepared to co-operate. Since health units meet the needs better than any other rural health organization, it seems reasonable that they should be established as rapidly as practicable.

(c) *Small in area*.—In a large country a health unit may seem to reach only a small group of people as compared with the total population and as a consequence a large majority of people will thus be deprived of any health service. On the other hand, if the health unit staff should be spread out to reach these other people, the workers would be so

widely scattered that it would not be possible to do any effective health work. As a result no good would accrue to the people in any part of the district.

In health unit work in rural areas, it is possible to carry out intensive activities and thus accomplish definite results. This is usually not feasible in a district plan. Health units act as a stimulus to other areas, set an example of effective work and tend to bring to other health work higher standards of excellence.

The district work in Ceylon has much improved since the advent of health units.

Other criticisms have been offered, but they were mostly of a trivial nature. All real criticisms have ceased when a health unit has been visited and its work given careful study.

Based upon experience health units are suitable for Ceylon and it is the purpose of the government to develop this type of work. Given a fair trial, health units may meet the needs of other states or countries.

APPENDIX I

HEALTH UNIT—PARANAKURU KORALE

Statement of expenditure—January-December, 1931

Central Government

Number	Description	Salaries	Allowances	Total	GRAND TOTAL

JUNE

THE SYNTHETIC ANTI-MALARIAL COMPOUNDS

THE time may eventually come when all galenicals and natural alkaloids in the world pharmacopœias—or perhaps by that time there may be only one universal pharmacopœia—have been replaced by their synthetic equivalents, or entirely displaced by new and more powerful synthetic drugs. So far we have not gone far along the road towards this ideal—if we accept the chemists' point of view—state of affairs, but a beginning has been made; for example during the last few years a large number of synthetic preparations which closely resemble cocaine have been introduced for local and spinal anaesthesia and now the synthetic quinolin derivatives are making a bid for the quinine market.

For centuries the cinchona alkaloids have held the field, almost unchallenged, in the treatment of malaria. Many specifics have appeared and have enjoyed varying periods of popularity, but the majority of these have contained cinchona alkaloids as their principal ingredient, and if they have not their popularity has been very short-lived. However, very soon after the introduction of plasmochin it became apparent that the privileged position of the cinchona alkaloids was likely to be challenged in the near future. At the time of its introduction it was repeatedly pointed out, both by its originators and by those who used it in the first clinical trials, that plasmochin did not represent the last word in synthetic compounds for the treatment of malaria but was the one that hitherto had given the most promising results of some thousands of closely allied compounds prepared in the I. G. Farbenindustrie laboratories at Elberfeld. The work of selecting from these the compounds that are likely to be efficacious in human malaria is in some ways a task calling for as much ingenuity as did the original preparation of the compounds. It is out of the question to do this testing on man, and plasmodium and hæmoproteus infections in birds have so far presented the best opportunity. Professors Roehl and Kikuth have more than justified this method of selecting these drugs by their successes up to date. Writers who emphasize the disparity between laboratory and field experiments—sometimes in words which suggest that they alone have realized this difference—appear to have forgotten that before a drug can be tested in the field it must go through the processes of selection in the laboratory and then trial under carefully-controlled hospital conditions. The drugs that have been issued by the Elberfeld laboratory

up to the present have had the most conscientious testing as to their safety and their efficacy before they have been allowed to come into the hands of the general medical public. Even then as there are racial and individual variations in the constitutions of human beings it may take many years of very extensive trial before all the possible reactions of man to a drug have been experienced. Few of the new powerful specifics are really fool-proof, and it is essential that in the early stages of our experience with them even field experiments should be very carefully supervised by competent doctors; where this cannot be done, it is better for all concerned that the experiment should not be undertaken.

Plasmoehin was issued to the general medical public about 7 years ago; in some ways it has fallen short of the expectations of its originators, in others it has exceeded them. It was found that in the doses originally advocated it produced toxic, sometimes dangerous and even fatal, symptoms in certain individuals, and that therefore it was necessary to administer it under strict medical supervision. But on the other hand it was found that the original dose advocated was unnecessarily high, that a much smaller dose was almost equally efficacious, and that by the addition of a small quantity of quinine the curative value of this smaller dose of plasmochin could be raised to the maximum level. Then again it was found that plasmochin had little if any effect on the asexual forms of *Plasmodium falciparum*; but on the other hand it was shown that in very small doses it destroyed the sexual forms and that in even more minute doses it sterilized the parasite so that further development did not take place even if this parasite were taken up by a carrier mosquito. From the time that this observation was made plasmochin has attracted the attention of the sanitarian who has seen in it a new weapon. Hitherto it was only possible to break the malaria infection cycle by attacking the mosquito transmitter, because the cinchona alkaloids had no direct effect on the gametocytes, the stage of the parasite that infects mosquitoes. Anti-gametocyte treatment is now a practicable sanitary measure, but it is not a universally-applicable one, any more than is larval control; there are places where one measure is applicable, there are places where the other is applicable, there are a few places where both are applicable, and unfortunately there are probably a much larger number of places where neither is applicable. Larval control has been practised since the time when Ross made his great discovery; it has had its triumphs and its failures. The failures, when properly and honestly reported, have added more to our knowledge of the subject than have the successes. There is still much to be learned about mosquito control, but the malariologist of to-day has so many facts at his disposal that when confronted with

a malaria problem he is in a position to give an opinion as to whether or not some form of mosquito control is likely to be of value, and further to say which particular method should be adopted in the circumstances.

On the other hand effective anti-gametocyte treatment is a new measure which has not yet had a sufficiently long trial to justify any dogmatic opinion. Trials have been carried out and very promising results have been reported; some of these reports have appeared in our pages. On theoretical grounds the main objection to the anti-gametocyte method is that it is a matter of all or nothing.

Many years ago Ross, tackling the malaria transmission problem from a mathematical point of view, concluded that in a given area provided the mosquito population were reduced below a certain level malaria would eventually die out, but that if the mosquito population were above an effective level the introduction of one gametocyte carrier would eventually lead to the infection of the whole community; or in other words that the aim of mosquito control need not be to destroy the last carrier mosquito but only to reduce the mosquito population below the effective level, and on the other hand that the aim in gametocyte control must be to remove the last carrier or the measure would be a failure.

The first part of this conclusion has for many years been accepted as an axiom, and—since complete eradication of the carrier species is usually impossible—on it much of the malaria control throughout the world is based. The second part of the hypothesis nobody has yet satisfactorily refuted on paper, and, in view of the fact that in certain places, such as Punjab villages, where in the inter-epidemic periods the gametocyte-carrier rate falls as low as 0.1 per cent, epidemics occur whenever the carrier-mosquito rate rises above a certain level, and that in endemic areas such attempts as have been made at gametocyte control have been so unsuccessful, it has been tacitly assumed that in this Ross was also correct. The past failures of gametocyte control were obviously due to the ineffectual methods that were used, but now there is an opportunity of testing this hypothesis properly.

The ideal conditions for testing the value of gametocyte control are a heavily malaria-infected community, living in isolation and separated from their nearest neighbours by a distance greater than the range of the carrier mosquitoes in the district, and under a fair degree of discipline. Discipline is a very essential factor as without it a number of persons will evade treatment and the experiment will be vitiated. Now these are very special conditions and it is probably very seldom that they can be complied with, but as we have said it is only in *theory* that this is an all-or-nothing measure, and although Ross's hypothesis has not been disproved it has not yet been proved,

practically, in an endemic area, so that it is possible that an antigametocyte control scheme which falls short of perfection might produce an appreciable effect on the malaria in a community.

An experiment has recently been started in Bengal which consists in attempting to control malaria in a certain area by anti-gametocyte measures. This area covers certainly not more than 20 square miles; if it were completely round (which is the best shape it could be from the point of view of the success of the experiment), the periphery would be nearly 16 miles in extent and $2\frac{1}{2}$ miles the greatest distance any one person would be from this periphery; there is little in the way of natural barriers to prevent free intermixing of the inhabitants with others outside the area, and no measures to restrict movement could possibly be taken; and finally the population is the ordinary rural population of Bengal, under no sort of discipline. Whole-hearted co-operation of the people is expected and will no doubt be obtained in many of the villages, but in a population of 20,000 there are certain to be some who will consider the scheme a government measure designed to annoy them and will refuse to take their plasmodium, or let their children take it. Thus, on the *theoretical premisses* outlined above, the experiment must be a failure. There are however a number of people who think that there is a considerable chance of its being a success. We sincerely hope that they are right, but we are ourselves not prepared to prophesy the result; time will show this. If it is a success we shall have to conclude that the theoretical premisses were wrong, that in anti-gametocyte control it is not a matter of all or nothing, and that an extensive anti-gametocyte campaign can achieve a degree of success even under very unfavourable conditions; on the other hand if it is a failure we shall not know wherein it has failed, whether the failure was due to a large number of persons escaping treatment, whether it was due to the normal interchange of population and the introduction of untreated gametocyte carriers, or whether it was due to the invasion of infected mosquitoes along the relatively very large periphery of the area under experiment, but it will certainly do nothing to prove that anti-gametocyte control in general is a failure as a sanitary measure.

The success of plasmodium as a gametocytocidal drug has overshadowed its more limited success as a schizonticide and as a drug for the treatment of the malarial attack; it was however in this rôle that it made its *début*. In the treatment of benign tertian malaria it scored a very striking success, and the fact that to obtain the maximum effect it is necessary to combine it with quinine does not detract from its value. The relapse rate in benign tertian malaria has always been over 50 per cent, usually about 70 per cent, whatever course of

quinine has been given; plasmochin alone has reduced this to 30 per cent, and combined with quinine—according to Sinton and his colleagues—a cure rate of 91 per cent may be achieved with a single course, even in persistent relapsers. Against the schizonts of malignant tertian it appears to have very little if any action at all. Again its value as a practical personal prophylactic has not been established. About two years ago James, Nicol and Shute staged an experiment to test its prophylactic potentialities but the dosage they used was not a practical one and Swellengrebel and others have since shown that in doses smaller than those James employed, but still too large for daily administration, it has no prophylactic qualities.

About two years ago we were told by someone who had attempted to summarize the literature on plasmochin that there were 400 papers in medical journals on the subject, and as they have been increasing by geometrical progression, it will be safe to estimate that the figure has now reached a thousand. It cannot therefore be said that the medical profession as a whole has neglected this drug or failed to appreciate its advantages and its limitations; the latter have been very clearly defined in a number of papers, and they are scarcely a matter of controversy, but there is still, in India at any rate, a surprising amount of misunderstanding on this subject amongst members of the medical profession and therefore not unnaturally amongst the laity also. Plasmochin is frequently prescribed purely as a curative measure in the treatment of malignant tertian malaria; usually the patient is saved by the fact that quinine is added, but we have heard of cases in which plasmochin alone was given with disastrous results—not brought about by the plasmochin itself but by the untreated malaria infection. The resident in the tropics—more especially the European resident—often considers that it is as unnecessary to consult a doctor when he has malaria as it is when he requires a dose of salts; (we do not admit that he is right in this, though circumstances will often make self-treatment necessary;) with quinine he was fairly safe as the subjective symptoms of overdosage are well known, very obvious and far from pleasant, but this is not the case with plasmochin, and the patient may not associate his symptoms with the drug he is taking. Cases have recently come to our notice where a patient, who has had plasmochin prescribed once by his doctor, has subsequently purchased it, treated himself, and eventually come to hospital with marked cyanosis, dyspnoea and a *Plasmodium falciparum* infection; in other cases the patient has taken plasmochin daily over long periods as a prophylactic measure. The following illustrates what may happen when laymen act without advice:—

A planter living in a malarious district took a tablet of quino-plasmochin (containing 0.01 gramme of

plasmochin) daily for two years as a prophylactic measure; during this time he remained quite free from fever. When he obtained a fresh supply he was given tablets of plasmochin simplex by mistake; these tablets contained 0.02 gramme of plasmochin. He noticed that the tablets were smaller than those he had been taking and proceeded to double the dose, that is, to take two tablets at a time. He then had an attack of malaria, and by way of treatment he decided to take his two tablets three times a day. Thus, in the place of the original 0.01 gramme daily, he was now taking 0.12 gramme of plasmochin, and he continued to do this until he became seriously ill.

The time has passed when it can be said that plasmochin should only be given under hospital conditions. We know that in effective doses it can be given under field conditions, but, as personal idiosyncrasy is far from uncommon, a course should not be prescribed unless the patient is under medical observation, or unless previous experience has shown that with the dosage prescribed the patient is not susceptible.

It is now a little over a year ago that atebirin, another synthetic compound chemically allied to plasmochin, was put on the market. In its action atebirin is much more closely allied to quinine, as it destroys the schizonts of all three species of malarial parasite. The immediate success of this drug was due to the fact that it was issued by the Elberfeld laboratories and that it had already been given a very extensive clinical trial in Germany, England, India, America, the Federated Malay States, and many other countries, from all of which uniformly satisfactory results were reported. It was found to destroy the schizonts of all three species of malarial parasite and to be far more efficacious in the prevention of relapses than quinine; Green at Kuala-Lumpur in a mixed series of 50 cases had no relapses after a seven-days course, and Thonnard-Neumann in Columbia also had a hundred per cent success after a five-days course in the same number of cases. Probably the most striking results were obtained by James and his co-workers in England in the treatment of induced malaria, where with a five-days course he cured patients who had proved entirely refractory to prolonged treatment by quinine. These first reports on atebirin were so complete and so consistently satisfactory that there was little left to be said in praise of the drug and the more recent publications have been concerned mainly with its short-comings. We have received reports of the frequency of relapses following atebirin treatment, but these have been mostly from malaria-endemic areas where the possibility of re-infection was very great. Working with monkeys, we ourselves have found that after an infection has been controlled—that is, kept at a sub-clinical level but not completely eradicated—by treatment or by the animal's natural powers of resistance, it is almost impossible to superimpose a second infection, but if the animal is completely cured by a thorough course of treatment then it is re-infected easily. It is possible that the same

thing occurs in man and that after completely effective atabrin treatment re-infection occurs more readily than after partially effective quinine treatment. On the other hand it is possible that in certain endemic areas, such as Assam and Bengal, the local strain of parasite is more resistant to treatment, as James found with certain Italian strains. We have every reason to believe that the toxicity of atabrin is very low and that it will be possible to give a longer course and larger doses than have been given in most cases up to the present. A monkey weighing 4 kilogrammes will tolerate a dose half the size of that usually prescribed for an adult man, and hitherto few serious symptoms have been attributed to atabrin alone. Some misunderstanding has arisen with regard to the discoloration of the sclerotics by atabrin, which is a yellow dye, and by its excretion in the urine; jaundice and hæmoglobinuria have been reported in such cases. Again, atabrin has a depressing effect on some people and in a few gastric discomfort has been noticed after the standard dose; this has been more frequently observed when it has been combined with plasmochin. Recently, a curious incident occurred in a tea garden in Assam where an experiment of treating the whole force with atabrin and plasmochin was being attempted; about 60 per cent of the coolies reported sick with various symptoms before the treatment was completed. The superintending medical officer of the group of gardens to

which this one belonged lived some miles away and, as the experiment was made during the rains when the roads are almost impassable, he could not supervise the scheme personally nor was he able to investigate the 'incident' personally until some days later; some of the coolies had already been found to be malingering and when he arrived on the scene all the patients had recovered. Unless some serious mistake were made in the dosage, which is very unlikely, the simplest explanation for the incident is that a few coolies had genuine abdominal pains, vomiting, and diarrhoea, which may or may not have been caused by the drugs they were receiving, and that the rest were thrown into a panic by the appearance of so-called jaundice and the dark coloration of the urine. Most of the workers who have reported their experience with atabrin have emphasized the absence of any disagreeable symptoms following its administration, but it is possible that instances of personal idiosyncrasy will be encountered from time to time, and that in the presence of certain pathological conditions it may be advisable to withhold this drug; time and experience alone will settle these points.

As a beginning has now been made the succeeding years may bring forth even more efficacious synthetic drugs for the treatment and prevention of malaria; there is no suggestion that the introduction of atabrin is more than another step along the road that leads to Ehrlich's ideal.

'SWINEY' PRIZE FOR WORK ON JURISPRUDENCE

THE Council of the Royal Society of Arts give notice that the next award of the Swiney Prize will be in January 1934, the ninetieth anniversary of the testator's death. Dr. Swiney died in 1844, and in his will he left a sum of money to the Royal Society of Arts for the purpose of presenting a prize, on every fifth anniversary of his death, to the author of the best published work on jurisprudence. The prize is a cup, value £100, and money to the same amount.

The award is made jointly by the Royal Society of Arts and the Royal College of Physicians. The prize is offered alternately for medical and for general jurisprudence. If at any time the joint committee of the Royal Society of Arts and the Royal College of Physicians, which is appointed to submit a book to the adjudicators, is unable to find a work of sufficient merit in the class whose turn it is to receive the award, it is at liberty to recommend a book belonging to the other class.

On the last occasion of the award in 1929 the prize was awarded for medical jurisprudence. It will, therefore, be offered on the present occasion for general jurisprudence.

Any person desiring to submit a work in competition, or to recommend any work for the consideration of the judges should do so by letter, addressed to the Secretary of the Society, John Street, Adelphi, London, W.C.2, not later than 30th November, 1933.

THE FACULTY OF TROPICAL MEDICINE, BENGAL

At the examination for the Diploma of Tropical Medicine (D.T.M. Bengal), held at the Calcutta School of Tropical Medicine in March 1933, the following 33 out of 38 candidates were successful:

Passed with distinction

(In order of merit)

- Sudhangshu Kumar Gangopadhaya, M.B. (Cal.). Awarded the 'Chuni Lal Bose' Gold Medal, 1933; private practitioner.
- Trambaklal Hergovind Trivedi, L.M.P. (U. P.), L.T.M. (Bengal), Sub-Medical Officer in-charge, Laboratory, Government West Hospital, Rajkot.
- Maneck Jamshedji Mehta, M.B.B.S. (Bom.), D.P.H. (Cal.), Officiating 3rd Assistant Port Health Officer, Calcutta.

Passed

- Arjan Singh Man, L.S.M.F. (Punjab), L.T.M. (Bengal), L.M.D., Sub-Assistant Surgeon, Government of India.
- Binoy Krishna Banerji, M.B. (Cal.), private practitioner.
- Manindra Nath Basak, M.B. (Cal.), private practitioner.
- Barendra Nath Basu, L.M.F. (Bengal), L.T.M. (Bengal), Medical Officer, Graham Charitable Dispensary, Darsona, Nadia.
- Phanindra Nath Basu, M.B. (Cal.), private practitioner.
- Rabindra Nath Biswas, M.B. (Cal.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), private practitioner.

- Pankaj Kumar Chatterji, M.B. (Cal.), private practitioner.
 Saroj Kumar Chatterji, M.B. (Cal.), private practitioner.
 Indu Bhushan Chaudhury, M.B.S. (Patna), private practitioner.
 Braja Gopal Choudhuri, M.B. (Cal.), private practitioner.
 Arthur Edward Ray Coombes, Diploma, Medical College, Madras, I.M.D., Assistant Surgeon, Government of India.
 Manohar Lal Dang, L.M.P. (Agra), L.T.M. (Bengal), I.M.D., Sub-Assistant Surgeon, Government of India.
 Dhan Singh, L.S.M.F. (Punjab), I.M.D., Sub-Assistant Surgeon, Government of India.
 Henry Louis Francis, L.M.F. (Bengal), L.T.M. (Bengal), I.M.D., Assistant Surgeon, Government of India.
 Gurkirpal Singh, L.M.P. (Agra), L.T.M. (Bengal), I.M.D., Sub-Assistant Surgeon, Government of India.
 William Lawrence McKenzie, Diploma, Medical College, Madras, I.M.D., Assistant Surgeon, Government of India.
 Sailendra Nath Mukherji, M.B. (Cal.), private practitioner.
 V. Narasimha Moorthy, M.B.S. (Mysore), D.P.H. (Cal.), Health Officer, Mysore State Service.
 Susil Kumer Neogy, M.M.F., M.D. (Cal.), private practitioner.
 Edward Gerald O'Flynn, Licentiate Medical College, Madras, L.T.M. (Bengal), I.M.D. Awarded the first prize in Entomology, Assistant Surgeon, Government of India.
 Gopal Chandra Pattanayak, M.B.S. (Patna), private practitioner.
 Samala Ramakrishna Reddy, L.M. & S. (Osmania Medical College, Hyderabad), Sub-Assistant Surgeon, Osmania Hospital, Hyderabad.
 S. A. F. Shamsul Huda, M.B. (Cal.), D.P.H. (Cal.), private practitioner.
 Narendra Nath Saha, L.M.F. (Bengal), Medical Officer, Barat U. B. Charitable Dispensary, Faridpur.
 Kailash Behari Sahay, M.B. (Cal.), Assistant Surgeon, Government of Bihar and Orissa.
 Jitendra Nath Sen, M.B. (Cal.), Assistant Surgeon, Government of Bihar and Orissa.
 Sachansu Kumar Sen Gupta, L.M.F. (Bengal), private practitioner.
 Ram Narain Sharma, L.S.M.F. (Agra), L.T.M. (Bengal), Medical Officer in-charge, Infectious Diseases Hospital and Public Health Laboratory, Agra (Municipality).
 U. Thant, L.M.P. (Burma), Sub-Assistant Surgeon, Government of Burma.
 Charles Louis Thompson, Diploma, Grant Medical College, Bombay, I.M.D., Assistant Surgeon, Government of India.

THE LICENCE IN TROPICAL MEDICINE

THE classes for this licence commence on 15th July at the Calcutta School of Tropical Medicine. The course lasts for about three months; this period includes the examination which commences on about 7th October.

There are this year a few vacancies, as, in the interests of economy, the various governments have not deputed the usual number of their servants to take the class; doctors wishing to take advantage of this opportunity, which would not occur in ordinary times, are advised to apply as early as possible to the director of the school.

FIFTY YEARS AGO

(From the *Indian Medical Gazette* of June 1883, Vol. XVIII, p. 166)

CONSUMPTION has always engaged the medical mind deeply; for to one or other of its forms the death of about one-fifth of the adult population of Great Britain is due; and its treatment has been, from the earliest era of medicine until now, eminently unsatisfactory.

* * * * *

Recent study and research concerning tuberculosis bear upon a larger question, that of the parasitic origin and causation of disease, and if it were once firmly established that tubercular consumption is due to inoculation or infection by a parasite organism, the way would be cleared to the demonstration and belief that many other forms of disease, more especially those with which micro-organisms have been found to be associated, are similarly caused. The germ theory being once placed on a stable footing, treatment, preventive and curative, by germicides would become an imperative necessity, and the only questions remaining for solution would be—what are the most effective germicides for particular varieties of pathogenic organisms, and how can they be most effectively applied in the special circumstances of each disease?

* * * * *

If phthisis is due to a bacillus, destruction of this bacillus outside of the body should prevent its spread, and destruction inside the body thwart its progress. The enemy has accordingly been attacked by a host of germicides conveyed through the blood, or more directly by means of 'naso-oral respirators' through the air tubes; but it has been shown that tubercle is practically extra-vascular, and doubt has been thrown upon the power of the respirators in use to yield a sufficient amount of the drug with which they are charged to be of any practical use.

This subject may therefore also be considered *sub judice*.

Current Topics

Carriers of Enteric.

(Abstracted from the *Lancet*, 11th March, 1933, p. 535)

ENTERIC carriers may be classified according to the duration of the carrier state, and also according to the route of excretion of the specific organisms. It has been shown that, in paratyphoid B infections especially, the incidence of temporary carriers in convalescence is high, and the report therefore lays stress on precautions against the spread of infection during the convalescent period. In some cases the carrier state may set in several months after convalescence, and its occasional intermittency is also a factor which adds to the difficulties of control; intervals of infectivity 'may be

separated by non-infective periods of years'. Most of those who continue to excrete bacilli for six months after the acute attack will continue to do so. Those who still excrete after a year, fortunately a small proportion only, will not clear spontaneously; the carrier state becomes chronic or permanent. The chronic carrier after a known attack of enteric fever is sufficiently dangerous, but in the investigation of an outbreak the history of the illness at least provides a clue to a possible source of infection. More dangerous, because more elusive, is the chronic carrier who has had no known attack or whose carrier state is intermittent. The two main routes of excretion are faecal and urinary; it is also well recognized that bone sinuses, or subcutaneous abscesses, may continue to yield pure cultures

for long periods. The chronic faecal carrier or excretor is 'usually a married woman of 30 years of age or upward'. Female chronic carriers exceed male carriers in the proportion of four or five to one. Children rarely become chronic carriers, but are important agents in dissemination because the attack is so often mild and atypical. Faecal carriers, who are occasionally 'mixed' carriers of *B. typhosus* and *paratyphosus*, are far the most numerous class and may be further subdivided into the biliary carrier (gall-bladder or liver and bile-ducts, or both) and the rare true intestinal carrier. Although chronic cholecystitis, usually but not always associated with gall-stones, has been found in a large proportion of faecal carriers, cases have occurred in which the biliary system could be held blameless, the focus being strictly intestinal. Not only may gall-stones be absent but the gall-bladder may show comparatively slight naked-eye changes such as thickening of the mucosa. Histologically, the most marked change observed by the authors of the report consisted in 'localized and diffuse collections of cells in the mucosa, which are mainly plasma cells and lymphocytes with scanty eosinophiles'. They think there is considerable support for Garbat's view that the gall-bladder in these carriers acts as a 'test-tube containing the bile medium in which the typhoid bacteria propagate without affecting the gall-bladder itself'. Urinary carriers, although less numerous, are clearly more dangerous than faecal carriers. Not only are the opportunities for spreading infection greater, but the organisms occur in large numbers in the urine and not uncommonly in pure culture. The nidus of infection appears to be 'most commonly situated in the kidney or kidney pelvis'. That one kidney only may be infected has been shown by means of ureteral catheterization and the clearance of the carrier state after the removal of the unilateral lesion.

Apart from careful treatment and nursing and the provision of a high caloric diet during the acute and convalescent stages, is it possible to prevent or lessen the possibility of the patient becoming a carrier? Prophylactic inoculation diminishes the incidence of clinical attacks. When attacks do occur in the inoculated they tend to be slight, and it has been held by some that carriers after such modified attacks are less numerous. Others, however, have not been able to confirm this. General anti-enteric inoculation of any population liable to exposure is not practicable in peace-time. But the same measure applied to closed communities such as the staff and inmates of mental hospitals is not only practicable but highly desirable. Professor Browning and his colleagues point out that although this measure be adopted the carrier must still be searched for and treated, since amongst the recently vaccinated massive infection may yet result in an epidemic. It is well known also that the protection afforded by inoculation with T. A. B. tends to wane after a year, and to secure full protection thereafter the process must be repeated. It is advised that in addition to bacteriological evidence of freedom from infection before discharge of a case from hospital, examinations should again be made six to twelve months later, compulsory powers being exercised by all authorities in order to obtain the necessary specimens from convalescents and suspects. In Scotland under the Public Health Regulations, it is possible to notify and to remove compulsorily a carrier, subject to the certificate being renewed every three months. In England powers exist merely to prevent enteric carriers from being concerned in the preparation or handling of food or drink for human consumption. In America regulations for the control of carriers are much more comprehensive and drastic. The authors of the report consider that the existing accommodation, usually an isolation hospital, for the investigation and treatment of carriers involving bacteriological, radiological, urological, and operative procedures is not adequate. This is certainly true of many small fever hospitals, but several of the large institutions already possess, or can readily provide, the necessary facilities.

In the treatment of the chronic faecal carrier chemotherapy, physiotherapy, and the administration of *B. acidophilus*, with a view to changing the reaction of the intestinal flora, alike proved ineffective. Vaccine therapy, including Besredka's oral bile vaccines, produced no better results. Where the gall-bladder is the site of infection cholecystectomy has been successful in terminating the carrier state in 75 per cent of cases. Failures may have been due to the fact that the patients were purely intestinal carriers who cannot be detected with certainty before operation. It seems clear that just as the chronic carrier state in diphtheria is most certainly terminated by the removal of infected tonsils and adenoids, so surgical measures offer by far the best chance of success for the cure of the chronic enteric carrier. In both conditions much expenditure of time and money will be saved when this fact is generally recognized.

The Position To-day of Tuberculin in Treatment

By R. A. YOUNG, M.D., F.R.C.P.

(Abstracted from the *British Medical Journal*, 17th December, 1932, p. 1091)

THE introduction of tuberculin was one of the great tragedies of medical research. Premature in its birth, damaged by the excessive zeal of its earliest exponents, or foster-parents—for Koch himself was cautious in his original claims—it has received the fate of the cripple, at times excessive care, at others neglect. Forty-two years have elapsed since its first introduction, and it remains a baffling and elusive enigma, in spite of an almost incredible amount of investigation, scientific and otherwise. To-day some authorities claim that it is not specific in its effects, and that it should be entirely discarded in treatment. On the other hand, there are enthusiasts who claim a specific and curative action for it and recommend its use widely, while there are others who have used it continuously for many years and are convinced that it has a definite though limited value. The time would therefore seem ripe for a critical and practical review of its effects in treatment. If this discussion could serve to clarify the position, especially to determine which of the three attitudes I have just mentioned is the correct one, then a notable success will have been achieved.

I should like to put forward the following points for discussion:

1. Is tuberculin useful in treatment?
2. If so, what are the indications and contra-indications for its use?
3. What forms is it best to employ?
4. Dosage—spacing and limit of doses.
5. How should it be given?
6. How does it act?

TUBERCULIN IN TREATMENT

It may be worth while to consider briefly certain opinions concerning tuberculin.

(a) It is generally accepted that it is completely innocuous to a healthy non-tuberculous person, even in large doses, while in those who have been infected it produces the well-known tuberculin reaction with its three effects—local, focal, and systemic—in greater or less degree, depending on the form employed and the method of administration. It has been supposed until recently that this reaction is specific, and that it is an allergic phenomenon. Both of these contentions have now been called in question, since other protein substances are said to produce a positive reaction in tuberculous patients, and the skin effects have been stated to be due to a general non-specific hypersensitivity to toxic substances in this disease.

(b) It is significant that its routine use has been greatly restricted in many sanatoriums, and entirely discarded in others; it receives scant mention in most textbooks of medicine and in special manuals on diseases

of the chest. Fishberg, in the latest edition of his well-known textbook, joins the ranks of those who advise against its use; he does so on the grounds that it is not certain that its action is specific, that it is difficult to estimate accurate dosage, especially of different preparations, and that it is altogether wanting in therapeutic effects when given in infinitesimally small doses, and may be decidedly harmful in large amounts.

(c) I have always been much impressed by the fact that, in the so-called surgical localizations of the disease—that is, in glands, bones, joints, and the ocular and genito-urinary systems—tuberculin has a considerable vogue, and that, in these conditions, it is the three well-known preparations of Koch which are chiefly employed, whereas in pulmonary tuberculosis the varieties and modifications of tuberculin which have been advocated are remarkably numerous, extending to more than a hundred. This has always suggested to me that there must be some fundamental difference between medical and surgical tuberculosis, and it is evident that the effects of tuberculin have been disappointing in the strictly medical cases, notably in pulmonary tuberculosis. The fact that so many attempts have been made to modify tuberculin for medical as opposed to surgical use in treatment suggests that it has been found wanting in some respects. On the other hand, I cannot but feel that if it were entirely useless it would have been discarded long ago, and would not be the subject of a serious discussion forty-two years after its introduction. My own experience would lead me to believe that tuberculin has definite therapeutic uses, and that these are considerable in the localized or surgical manifestations, and strictly limited in the pulmonary forms of the disease.

INDICATIONS AND CONTRA-INDICATIONS FOR ITS USE

In cases of pulmonary tuberculosis I have only found tuberculin useful in those patients in whom the disease has progressed satisfactorily towards arrest, but who are left with a small amount of expectoration containing tubercle bacilli. A short course of tuberculin may serve to get rid of the bacilli, to dry up the sputum, or to do both. Such effects alone, if established, would justify its use, since the patients are often enabled to return to their families and to their work without fear and without risk. Many employers will not take back a patient of whom it cannot be certified that the sputum is tubercle-free. Tuberculin has been recommended in chronic cases slow to settle down, of the type described by Inman as 'resting afebrile, ambulant febrile'. I am less sure of its value in such cases, and I think its effects require very careful watching; but it is worth considering. The patient should be kept in bed till it is clear that the tuberculin is not producing any severe reaction, and at the first indication that there is hypersensitiveness to it, administration should be stopped or the dose reduced. I am convinced that tuberculin is of great use in some surgical manifestations, notably in localized genito-urinary tuberculosis, particularly where such localizations coexist with chronic or latent pulmonary tuberculosis and where surgery is impracticable or inadvisable. In localized ocular tuberculosis it can be very helpful, if cautiously used, with the strictest control of dosage, in collaboration with an ophthalmic surgeon.

Tuberculin should not be given in those cases in which there is active, spreading, caseous disease, or recent active 'spread'; it is likely to be harmful by inducing a definite focal reaction, which cannot be controlled, and may be the means of increasing the softening of the caseous areas, or of spreading the disease. It should certainly not be given if there is any degree of continuous, remittent, or intermittent fever. The patient is already receiving more of the toxic products of the bacillus than he can deal with, and any administration of tuberculin is likely to do harm. It is generally recognized that it can only be harmful in any form of miliary tuberculosis, whether this be generalized or local. It should not be given if there is definite albuminuria

except where this is due to renal or vesical tuberculosis, since prolonged administration of tuberculin has been known to be followed by nephritis.

BEST FORMS IN WHICH TO EMPLOY TUBERCULIN

The varieties of tuberculin may be classified as follows:—

1. Filtrates of cultures concentrated, or otherwise modified, especially on glycerin broth media. Of these, Koch's original or old tuberculin is the type.

2. Extracts from the bacillary bodies—Koch's T.O. and T.R.

3. Emulsions of ground-up bacilli—Koch's new tuberculin or B.E. Various processes may be applied before emulsification, as, for example, in Dreyer's diaplyte vaccine, in which the bacilli are treated with formalin and afterwards with acetone, with a view to removing their acid-fast characters.

4. Vaccines made from living attenuated cultures, of which B.C.G. is the type.

It should be recognized that any of these varieties may be made from human, bovine, or other sources. In this connection I may perhaps note a fact which is not generally known, that the Therapeutic Substances Act, 1925, which is concerned with the preparation of many agents employed in treatment, restricts the name 'tuberculin' to the first of these groups, and advises the term 'tubercle vaccine' for any substance obtained directly from the bacterial bodies.

My own experience is limited to the three preparations introduced by Koch—namely, old tuberculin, tuberculin T.R. and B.E. There seems to be agreement on the bacteriological side that the tuberculin reaction does not vary in character with the preparation, though it may differ in degree. Attempts to detoxicate tuberculin or modify its toxic effects seem to succeed only in diminishing or destroying its beneficial effects. Personally I prefer B.E. for most medical purposes; it seems to be easier to control and to cause less severe reactions. In surgical cases, particularly tuberculosis of the epididymis, bladder, and prostate, I, in co-operation with my surgical colleagues, have used T.R. I have generally used the tuberculins or tubercle vaccines prepared from human bacilli, but in some ocular cases I have thought that bovine tuberculin has been effective where the human preparation has failed. It is sometimes recommended to start with the bovine tuberculin and later to transfer to the human preparation.

DOSAGE—SPACING AND LIMIT OF DOSAGE

The question of dosage is a difficult one. Believing as I do that tuberculin can be powerfully toxic and harmful if injudiciously given, I always start with infinitesimal doses in pulmonary cases, and I never increase the dose till it is clear that the patient is immune to the one last given. I aim at avoiding any general reaction, and therefore advise that the temperature be taken regularly for at least the day of injection and one or two days after. I usually begin with 1/500,000 mg., and if there is no reaction from this I give, three or four days later, 1/400,000 mg., and then, at the same intervals, 1/300,000 mg., 1/200,000 mg., 1/100,000 mg., or smaller increases if the patient is sensitive. After this the doses can be more rapidly increased—that is, 1/75,000 mg., 1/60,000 mg., 1/45,000 mg., and so on, but I usually extend the interval to seven days by this time. Provided there is no serious reaction and that there is clinical evidence of improvement, I am prepared to go on slowly increasing the dose at weekly intervals or sometimes at ten-day periods till I reach a dose of 1/500 mg., but I rarely go beyond this. Occasionally, when doses of this amount, or larger, are reached, severe local reactions may occur, with marked local infiltration in and under the skin and even caseation and softening. This need not necessarily interrupt the treatment, but suggests longer intervals or smaller doses. In surgical cases in which there is no pulmonary lesion it is not necessary to start with such small doses, and T.R. may be used

commencing with 1/10,000 mg., and working up by weekly doses to 1/1,000 mg., at which level it may be maintained for long periods.

Preventable Invalidism following Childbirth

By JENNINGS C. LITZENBERG, M.D.

(Abstracted from the *Journal of the American Medical Association*, 19th November, 1932, Vol. 99, No. 21, p. 1740)

THE ultimate welfare of mothers cannot be secured by good care during pregnancy and labour alone. Post-partum oversight is quite as important. The objects of motherhood are not attained by bringing a healthy baby to a living mother; they are completed only when that mother is restored to perfect health. Post-partum care must continue until that end is accomplished, whether it takes two weeks, two months or two years. Thus only can invalidism be avoided. The puerperium is too generally considered at an end with the termination of the lying-in period. It should be thought of as consisting of three periods:

1. *The immediate puerperium*.—This is the lying-in period, ending when involution has progressed far enough to enable the patient to be up and about. Every patient should be told that it takes an additional four or six weeks for her pelvic organs to return to normal. She will then appreciate the necessity of following instructions to be careful.

2. *The intermediate puerperium*.—This is the period of completion of involution. The restoration of all tissues involved in child-bearing to normal should be completed from six to eight weeks post-partum, but, unfortunately, this is frequently not accomplished.

3. *The remote puerperium*.—The period of complete restoration to health ends only when all delayed normal processes and every complication of pregnancy and labour have been entirely eliminated.

Time will not permit a detailed consideration of all the valuable procedures necessary in post-partum care, so discussion must be limited to only a few of the more important and too frequently neglected causes of invalidism following childbirth.

While the puerperium is supposed to be occupied chiefly with normal processes, these are so frequently altered and there are so many abnormal inheritances from gestation and parturition that it is often quite pathologic.

ANÆMIA

Anæmia is a common cause of slow recovery after delivery. Its treatment post-partum begins with prophylaxis at delivery, when the loss of blood must be limited to the smallest possible amount; more than 400 c.cm. is too much, and over 500 c.cm. is excessive. Because bleeding is normal after birth, one is too apt to think that even a considerable loss is unimportant. Measurement is the only way to be certain of the amount of bleeding. This can be done by any one, for it is not difficult. All but a small amount can be collected in a small basin. If you think that your patients are not losing too much blood, measure it—you may be surprised. Too much has been said about the ability of women to live following large losses of blood after delivery. We have been too content with saving the woman's life and not anxious enough about her health and the prevention of invalidism.

If bleeding is kept under 400 c.cm., the first post-partum step has been taken in conserving the mother's future health. The second step is examination of the blood after delivery to detect and treat an unsuspected anæmia. Women may live after tremendous bleeding, but one with a low hæmoglobin and red cell count is greatly handicapped in her restoration to perfect health and strength.

TOXÆMIAS

One of the richest rewards of prenatal care has been the saving of mothers by early discovery and treatment of toxæmias. An equally rich experience will

reward him who follows all his toxic patients for a considerable time, to make sure that there is no remnant of damage to the kidney. This is especially true in those cases in which the disappearance of albumin, casts and hypertension and the return of renal function have been prolonged. Nearly always, when recovery is slow, and even when it has been rather rapid, albumin and casts often appear periodically, which will go undetected and an insidiously developing nephritis may be missed unless the urine of every woman who has had toxæmia is examined frequently and long enough to give assurance that the kidneys have become normal. When recovery from toxæmia is slow, the kidneys have been seriously damaged, are more likely to develop nephritis and will be less able to carry the extra load of another pregnancy or any other condition throwing a severe demand on the kidneys.

DISPLACEMENT OF THE UTERUS

In spite of the fact that some women with retroversion of the uterus have no untoward symptoms, this is a source of invalidism in many more. Various authorities place the incidence of retroversion after delivery at from 20 to 40 per cent. In one thousand of my cases the frequency was 25 per cent. Many of these may be prevented by exercises in bed during the immediate puerperium. Other patients may be cured by simply replacing the uterus at the end of the lying-in period, at which time, whether there has been a displacement or not, the patient should be instructed to take moderate physical exercise, to do the kangaroo walk and how to assume correctly the kneec-chest posture. These, particularly the kangaroo walk, help to maintain the normal position of the uterus and not infrequently cause the retroverted puerperal uterus to return to the anterior position. Beck, when he introduced the 'kangaroo walk', proved, by a large series, each alternate one of whom was given the exercise, that those using it had fewer retroversions. An examination should always be made from four to six weeks post-partum. If, at this time, the retroversion persists in spite of its primary replacement and the physical exercises, the uterus should then be replaced and a carefully fitted pessary adjusted. In my series of one thousand consecutive deliveries, I found approximately one-fourth had retroversions at the end of the intermediate puerperium and that 90 per cent of these were cured by a properly fitted pessary. On the other hand, in a control series of gynaecological cases, not recently delivered, I failed to cure retroversions by the use of the pessary in 95 per cent, malposition recurring as soon as the pessary was removed. I also found that if the adjustment of the pessary was delayed even a short time beyond six weeks after delivery, the percentage of cures dropped rapidly until at the end of three months post-partum, failure was the rule.

NEUROSES

Many neuroses follow delivery, owing to a failure of the physician to appreciate that in the surroundings of modern civilization child-bearing is not always a normal process, often taxing a woman to the limit of her physical and nervous strength. Giving sufficient rest and time for recuperation of the general health, detection and treatment of anæmia and attention to general and mental hygiene, until nervous stability is restored, will avoid neurasthenia and psychosis.

INFECTIONS

Pyelitis and pyelonephritis.—Infections of the urinary tract are peculiarly frequent during pregnancy. Pus in the urine is always a danger signal. It should be eliminated promptly, for it possesses grave possibilities as a focus of infection and is particularly apt to result in chronic nephritis. Every case of infection of the urinary tract must be followed until every last trace of pus in the urine is removed, however long it may take. I have seen patients without any other evidence of infection in whom chronic nephritis developed and who

died because pyelitis of pregnancy was neglected after subsidence of acute symptoms and the patient was not followed to complete elimination of the infection of the urinary tract.

Puerperal infection.—It is not sufficient to treat puerperal infection only until fever, leucocytosis and localized evidence of the acute disease have disappeared, for frequently chronic pelvic and distant lesions are left which are dangerous to health and life. The acute infection, by extension into the immediate neighbourhood of the uterus, frequently leaves chronic consequences from pelvic cellulitis, metritis, salpingitis or peritonitis, and the blood-borne germs attack distant organs, resulting in chronic arthritis, grave cardiac lesions and chronic nephritis.

Chronic cervicitis.—Of the local pelvic lesions, the most common and persistent is chronic cervicitis, which, with its annoying leucorrhœa, follows nearly every case of childbed fever and occurs also in an inordinate number in which there has been no sepsis. Cervicitis is not a trivial lesion, but is a focal infection of far-reaching possibilities. Furthermore, chronic inflammation of the cervix is a dangerous disease, for, by its long-continued irritation, it is potentially a precancerous condition. The foundation of many a cancer is laid at delivery by lacerations with their consequent easy infection and by failure to cure a chronic cervicitis. Therefore, every child-bearing woman should be treated until all evidence of cervicitis has entirely disappeared because: (1) an infected cervix is, with its attendant leucorrhœa, an annoying disease; (2) it is a dangerous focus of infection, the same as the teeth or the tonsils, and (3) it is potentially a precancerous condition, for chronic irritation is the one ætiological factor in cancer about which there is general agreement. Therefore, one's first duty in preventing cancer of the cervix uteri is post-partum care to secure an uninfected, perfectly healed cervix by observation long enough to determine that the cervix heals spontaneously after delivery, and if it does not, to secure healing by local treatments, cauterization or repair of lacerations.

SUMMARY

The ultimate welfare of the parturient woman cannot be secured by good ante-partum and intra-partum care alone, but requires equally good post-partum attention:

1. Meticulous care is necessary during the lying-in period, and careful examination is essential at the end of it to detect and correct any abnormalities.
2. Care consists of, also, prevention of hæmorrhage at delivery and the discovery and treatment of anæmia post-partum.
3. Toxæmias must be followed to the complete eradication of all conditions which may lead to chronic nephritis.
4. Displacements of the uterus must be corrected, for a large percentage can be cured.
5. All infections must be followed to complete cure and elimination of chronic sequelæ as far as is possible.
6. Re-examination must be made at the end of the intermediate puerperium to discover recurrence or occurrence of abnormal conditions.
7. Observation must be continued until the mother is restored to perfect health, however long that may require.
8. If adequate post-partum care is not carried to its ultimate conclusion, the consequences may be grave anæmia, general ill health, nephritis, permanent displacements of the uterus, grave cardiac lesions, neurosis, psychosis, chronic cervicitis, cancer and death.

Is the Increase of Cancer Real or Apparent? A Study Based on the Statistics of Canada

By MADGE THURLOW MACKLIN, M.D.

(Abstracted from the *American Journal of Cancer*, September 1932, No. 5, Vol. XVI, p. 1193)

THE statement is frequently encountered that cancer is rapidly increasing throughout the world, the figures

which are brought forward to support this statement being the death rates from this disease per 100,000 of population. The percentage of total deaths which is attributable to cancer may be higher than it was formerly, but that is not in itself evidence that cancer, as such, is on the increase. A higher percentage of cancer cases may be due to the decrease of other causes of death. The death rates per 100,000 of population, however, are more convincing. Thus in all Canada in 1901 the death rate from cancer per 100,000 of population was 46.8; in the next two decades it had risen to 75 per 100,000 of the population, an increase of 62 per cent.

Is the Increase a Real One? This greater frequency has been said by some to be more apparent than real; by others it has been held to be an actual increase.

Various arguments are put forward by those who do not admit a real increase. In the first place, they state that the age of death has been raised, so that more people now live to the cancer age than formerly. In this connection they point to the great saving in lives of infants by social and medical agencies, so that they may live to the age at which cancer will develop. Secondly, there is put forward the idea that diagnosis is much better to-day than it was twenty years ago, so that more cases of cancer are diagnosed than was possible at that time. In the third place, vital statistics are increasingly accurate, another factor which tends to increase the number of deaths attributed to cancer. A fourth argument, which is really a part of the two preceding ones, might be presented, namely, that many more persons are attended by physicians to-day than was the case in 1901. With each year each of these factors operates in such a manner as to enhance still further the cancer death rate. Thus each year sees more infant welfare work undertaken, and a lowering of the death rate in the early years of life. Each year sees a progressively higher percentage of well trained personnel in the medical profession. Each year sees a spreading of medical attendance to a greater percentage of the population and to more and more outlying districts, with the result that statistics are becoming more and more reliable. For these reasons we should expect a steady increase of registered deaths from cancer, and from 1921, when the rate was 75, to 1929, the latest year for which Canadian statistics are available, this expectation has been fulfilled, for the rate has steadily risen until it was 90 per 100,000 for all Canada. If only the registration area of Canada as it was in 1921 be considered, the rate is 93.9 for 1929.

There are observations, also, which lead us to the conclusion that the increase in cancer is more apparent than real. Thus, for example, in 1928 Prince Edward Island had a cancer rate of 114, while Saskatchewan had a rate of only 55, or less than half that of the former province. When, however, we consider the age of the population in the two provinces, we see that in the one with the high cancer rate, 31.5 per cent of the inhabitants were over forty as contrasted with 19.6 per cent in the province with the low cancer rate; also that 13.3 per cent were over sixty in the former as compared with 4 per cent over sixty in the latter. While these percentages are based upon the 1921 census, and do not actually represent the percentages in 1928, nevertheless they indicate the tendency for a population with a high percentage of old people to show a much higher cancer rate than a population made up largely of pioneer families, in which the average age is much lower.

We may visualize mankind as walking over a bridge which spans the river of death. Along its length and width are many trap-doors, through which the unwary traveller may drop into the dark-flowing stream beneath. As the trap-door of infant mortality opens far less frequently than it did before; as the trap-door of yellow fever is practically shut; as the trap-doors of malaria and typhoid and smallpox open but once where they formerly opened a score of times, we find that the troop of people is not nearly so thinned out by the

time the middle of the bridge is reached as in years gone by. Even in the last half of the bridge, the trap-doors that once sprang open with alacrity, now move rustily on their hinges, and the throng which formerly dropped from sight through their hungry mouths now moves over them almost unaware of their existence. But it is a law imposed upon all those who start upon that journey, that they shall never reach the far side. At some time they must leave the crowd and sink into the river. Some of them almost finish the span, and the further they go, the fewer are the trap-doors to betray their footsteps; but at the end, although they are few, they are wide and long, and those who avoided the pitfalls farther back, now drop from sight through fewer doors, that yawn more widely.

Much has been done to lengthen the time which anyone may spend upon the bridge of life. In 1901 the average age of death in Canada was 31; in 1921 it was 38.5. If we exclude all those dying under 5, the average age of death was 49.5 in 1901, and 53.2 in 1921. In 1901 the death rate per 1,000 was 15; in 1921 it was 10.6. We must all die of something, and it is inevitable, as we eliminate one cause of death after another, that we increase the death rate from the causes that remain, for while we may increase the length of life, we do not decrease the certainty of death.

SUMMARY

Cancer is increasing, and it is increasing particularly in the age group over sixty. The reason for its increase is not that it is occurring at progressively younger ages, or attacking larger percentages of the younger population. Despite its increase, deaths are fewer from all causes now than they were. We have won more ground from the ravages of infectious disease than we have lost to those disorders which are dependent upon inherent qualities in the chemical and physical make-up of the individuals. Cancer is increasing because, by preventive methods, there has been created a larger population to grow old; and having grown old, they are kept from dying of those ills from which they formerly suffered. With each increase in the warfare against preventable diseases, there will be an increase in the ravages from cancer, for with each victory there is created a greater available population to die from that disease.

These conclusions are based upon the statistics of Canada. There is strong ground for believing that a similar analysis of the statistics of any other country would lead to the same conclusions. It is true that there may be racial differences in immunity to cancer, but the conclusion here reached will probably prove universal, namely that excellent public health measures and high cancer rates are inseparable, at least for the present. Those who point to the low cancer rates existing among primitive peoples, and who state that cancer is a disease of modern civilization, neglect to call attention to the fact that preventive medicine is itself a triumph of modern civilization.

Removal of the Spleen

By THE RT. HON. LORD MOYNIHAN OF LEEDS

(Abstracted from the *British Medical Journal*,

15th October, 1932, p. 701)

FUNCTIONS OF THE SPLEEN

THE functions of the spleen are not fully understood. Its activities may be grouped in relation to four separate systems.

The hæmopoietic system.—In embryonic life red cells and leucocytes are manufactured here—a return to this function is seen in the leukaemias and in infections in adult life. The Malpighian bodies give rise to leucocytes, and the endothelial cells of the splenic pulp may, under certain circumstances, proliferate and be thrown off into the circulation. It has been suggested that the spleen secretes a hormone which acts on the bone marrow; a rapid anaemia occurs after splenectomy, and

it is possible that this is due to the absence of such a hormone. An intraperitoneal injection of splenic extract in such a case has been shown to cause an increase in the red cells and in hæmoglobin. A substance which restrains the red cells has been supposed to be present, and its absence after splenectomy held to be the cause of the leucocytosis which constantly occurs.

The reticulo-endothelial system.—The spleen is the most important single member of this system. The pulp cells are capable of taking up foreign particles circulating in the blood stream, effete red cells, and perhaps also blood platelets and circulating organisms. Broken-down red cells are carried, probably in endothelial cells, to the Kupffer cells of the liver. Organisms such as the malaria parasite and *Spirochæta pallida* extracted from the blood may be stored in the spleen. The pulp cells have a further function in combating infections by the manufacture of immunizing substances, and it is for this reason that the spleen is constantly enlarged during the course of generalized infections; a lowered resistance to infections is one of the (theoretical) after-results.

The digestive system.—The volume of the spleen varies during the day, an increase occurring during the three or four hours after a meal. It may be that there is some connection between the variation in the size of the spleen and the leucocytosis which occurs during digestion.

The sympathetic-endocrine system.—The sympathetic nervous connections of the spleen are very intimate, and it has been shown that the injection of splenic extracts causes a contraction in smooth muscle. A connection has been suggested between the spleen, the thyroid, and the thymus glands.

INDICATIONS FOR REMOVAL OF THE SPLEEN

Rupture or laceration of the spleen.—Rupture of the normal spleen without injury has been recorded. This is a very uncommon type of lesion, and no explanation of it has been put forward. A series of thirteen cases has been collected, nine of which recovered after operation. Cases due to injury are far more common. There are cases where massive bleeding takes place immediately after the accident; the patient does not recover from the original shock, and death takes place in a very short time. Such cases are due to a tearing of the splenic vessels at the hilum of the organ, or to its actual avulsion. After laceration of the spleen the patient recovers from the initial shock of the injury, and signs due to internal hæmorrhage then make their speedy appearance. In a few cases the initial loss of blood is small, and symptoms of hæmorrhage are not observed until a second effusion of blood occurs. Operation must be undertaken as soon as the diagnosis is made, and the spleen should be removed. Splenectomy gives good results, a recent series showing a recovery rate of 93 per cent.

Movable spleen.—This condition is met with either as part of a general visceroptosis or when the phrenocolic ligament is unduly long. Attacks of severe and sudden pain may be experienced. A case is recorded where a movable spleen lying in the pelvis became twisted; the swelling which resulted caused impaction and intestinal obstruction owing to pressure on the rectum. In most cases relief can be obtained from a well-fitting belt, but in others an operation may have to be performed. As a rule fixation, though possible, is not so satisfactory as removal, which has little or no mortality and is followed by no appreciable disability.

Torsion.—Torsion may occur in a freely movable spleen. The blood supply is cut off, the organ threatens to become gangrenous, and a general peritonitis may result. Relief of the strangulation, and fixation of the spleen have been advocated, but removal of the spleen will probably be necessary in most cases.

Prolapse of the spleen.—Some of the earliest cases in the literature refer to removal of the spleen for prolapse, and the operation appears to have been

followed by recovery in most cases. This must be a rare accident even in war injuries, and splenectomy would only be called for in those cases in which the spleen was badly lacerated or infected. In other cases the spleen would be preserved.

Malaria.—Enlargement of the spleen may be a danger or a discomfort to its owner on account of liability to rupture from trivial injuries. The removal of the spleen may make the disease more amenable to treatment, and so help to cure it. The spleen may be mobile or firmly fixed; if the former, removal is simple and safe; if the latter, it is difficult and dangerous. The mortality is approximately 5 per cent in the former and 75 per cent in the latter condition.

Splenic anæmia.—It is time for the title 'Banti's disease' to be dropped. In Banti's own description I can hardly recognize conditions with which experience in this country has made me familiar. Splenic anæmia is a condition in which the spleen is enlarged, anæmia develops, hæmorrhages are common, the liver undergoes changes resulting at last in atrophy of considerable degree, and ascites is present. It is a continuously progressive disease, and in the absence of surgical relief is invariably fatal. Operation is the one opportunity of saving life. Its danger is directly dependent upon the stage which the disease has reached. In earlier stages the spleen is not greatly increased in size, anæmia is slight, and when the abdomen is opened the spleen is found to have few adhesions, none of them of great density. In later stages anæmia may be profound, the spleen gigantic, and adhesions of such character that their division seems at first almost impossible. In one case I had to remove a piece of the diaphragm, as a condition of cohesion rather than adhesion was present; a gap about two inches long was left in the diaphragm, but closure presented only slight difficulty, and the patient recovered.

There are few, if indeed there are any, operations in surgery which require such careful preparation of the patient. If the spleen is gigantic its size must be reduced by deep x-ray treatment, or preferably by the application of radium. In a few weeks a spleen which seems to fill the abdomen, and to show great salience, is reduced so much that only a slight projection is felt below the left costal margin. Anæmia, which may be profound, is always present, and is especially severe after any form of hæmorrhage; I have had many patients whose red cells did not number two million to the c.mm. Anæmia responds readily and rapidly to transfusion of blood, which may be repeated several times; on two occasions I have given blood five times before removing the spleen. When the general and local conditions are thus improved the difficulties of the operation are not, of course, reduced, but its dangers are much lessened. My mortality is between 6 and 7 per cent, and I attribute this to the care of the patient before operation. There is no hurry as a rule, and a couple of months may well be spent in making the patient safe for surgery.

The immediate mortality of splenectomy in this condition varies according to the stage of the disease and the competence of the operator; the technical difficulties are never, or rarely, overcome without great patience and resource. Bleeding from adhesions must be stopped by pressure with hot large swabs packed into the wound as tightly as possible. The average death rate in skilled hands is approximately 12 per cent. But in the late cases operation does not entirely free the patient from risks. Three of my patients have suffered from hæmatemesis some months or years afterwards, and on two occasions had to be admitted to hospital for transfusion; one of these patients has suffered from hæmatemesis on three occasions. This very disappointing experience makes it clear that operation must be practised at the earliest possible moment. Even in late stages, however, the recovery of the patient is often most remarkable. When the liver is found to be shrunken and hard, when ascites is present, and the outlook apparently almost hopeless, improvement begins

and is steadily maintained, and the patient finally appears to recover completely. There is no doubt that regeneration of liver cells in such cases must be considerable. On one occasion only have I had to tap the abdomen to remove fluid after splenectomy.

In general, it may be observed that success in this operation depends upon two factors: a careful preparation of the patient by the usual methods, especially by blood transfusion, and a reduction of the size of the spleen by application of x-rays or radium; the surgical outlook may so be considerably improved. Except in cases of splenic anæmia, the technical difficulties of the operation are inconsiderable.

Anæsthesia in Tropical Surgery

By C. GRANTHAM-HILL, M.B. (Camb.)

(Abstracted from the *Lancet*, 11th February, 1933, p. 295)

THE difficulty of obtaining good general anæsthesia for surgical operations has always been one of the constant trials of medical work in the tropics. This difficulty is particularly marked in a country such as the Anglo-Egyptian Sudan, in which there are great variations of temperature and humidity, a shortage of experienced medical staff, and a backward and primitive race supplying the majority of the patients. There is, amongst native Sudanese patients, an almost universal dread of losing consciousness under an anæsthetic, a dread compounded of fear of the unknown and a belief that the soul actually leaves the body and may have difficulty in finding it again. There is sometimes also a tincture of doubt as to what mutilation may be in store for the unconscious and helpless patient. The relief with which the information that an operation can be performed without loss of consciousness and without pain is received by such patients contributes greatly to that hopeful outlook which is of such enormous value in the treatment of the African native.

The technical, as apart from the psychological, difficulties of general anæsthesia may be summarized as follows:—

Chloroform, the most dependable of available anæsthetics, is nevertheless dangerous in unskilled hands, and few native medical officers become really dependable in its use. Further, its toxic effect in prolonged anæsthesia is a very real danger, particularly in view of the commonness of hepatic and renal deficiencies in tropical patients.

Ether is very unreliable owing to the great variation in its rate of evaporation following atmospheric changes. It loses bulk rapidly in hot weather, and is apt to explode. Its use needs considerable skill, especially when in combination with chloroform, for the relative strength of the two drugs is continually changing as the ether evaporates. Closed ether appliances seldom survive the climate for more than a few months, on account of the loss of elasticity of the rubber bags or connections. Ether readily causes bronchial irritation in hot, dry weather. The most useful mode of administration is by the rectum mixed with olive oil.

Nitrous oxide.—Both nitrous oxide and oxygen are impossibly expensive, as they have to be obtained from Europe, and the cylinders lose half their contents in transit.

Ethyl chloride is definitely dangerous unless given in measured quantity from a rubber bag, which rapidly loses elasticity.

Avertin has the very grave objection that skilled attention is needed for at least half an hour before operation, and often for 24 hours after it. It is therefore almost ruled out as a routine anæsthetic in the primitive conditions of nursing found in most parts of this country.

The solution of many of these difficulties has been found to lie in the increasing use of local and spinal anæsthesia; the following are the most striking of the many advantages:

(1) The minimum of shock with the maximum of relaxation.

(2) The almost complete absence of post-anæsthetic vomiting. This is of great value both from a physical and a psychological aspect. The patient usually sleeps well, and can take fluids and solid diet much earlier than after general anæsthesia.

(3) Preparatory and after-treatment are simplified. Many cases can be admitted and sent home on the day of operation, thus economizing beds.

(4) One skilled assistant the less is needed.

(5) The co-operation of the patient during the operation is often of great assistance—*e.g.*, a timely cough in locating a hernial sac and the movement of fingers in a tendon suture.

These advantages are, of course, familiar to all surgeons, but work at a distance from the refinements of skilled assistance and nursing lends them such added value as to warrant the emphasis used.

SPINAL ANÆSTHESIA IN ABDOMINAL OPERATIONS

Spinal anæsthesia is the anæsthesia of choice for major abdominal operations on patients who are not profoundly shocked, cachectic, or very old; in other words, for those who are reasonably good 'risks', and can tolerate the inevitable drop in blood pressure. After considerable experience of stovaine, novocain, and spinocaine, we have found neocaine, given by the method described by Koster and Kasman, the most reliable. Over 200 operations have been done under this anæsthetic in the Khartoum and Omdurman Hospitals without any untoward event referable to the drug, and with uniformly satisfactory results. Briefly, the method used is as follows:—

After a preliminary injection of morphia, the interval between the first and second, or second and third lumbar vertebræ is punctured with a fine needle and a quantity of cerebro-spinal fluid is drawn off and mixed with the crystalline neocaine in the glass ampoule in which it is supplied. The solution is then injected slowly through the needle which has been left in place.

For an adult of average weight: 10 mg. of neocaine in 4 c.cm. of fluid give anæsthesia up to the umbilicus; 15 mg. of neocaine in 6 c.cm. of fluid give anæsthesia up to the costal margin; 20 mg. of neocaine in 8 c.cm. of fluid give anæsthesia up to the clavicle.

Immediately after injection the patient is placed in the Trendelenburg position to counteract the cerebral anæmia which follows the invariable drop in blood pressure, and the operation may start within five minutes. Complete anæsthesia lasts for about an hour; if the operation is not completed within this time, novocain may be injected into the peritoneal edges, or a little chloroform given. If there is nausea or retching the head of the table is still further lowered and, if they persist, ephedrine is injected, though this is not often needed. After return to the ward, the head should be kept low until the pulse has recovered its volume. No cases of headache have occurred in this series. This is attributed to the use of a fine needle. The following case illustrates some of the advantages of this form of anæsthetic.

A male native, aged 35, was admitted with a history of sudden onset two hours previously of epigastric pain of an agonizing character, with vomiting and collapse. For two years previously there had been intermittent pain when the stomach was empty. There was board-like rigidity of the upper abdomen, a subnormal temperature, and a pulse-rate of 80, the pulse being of fair volume.

A preparatory injection of morphia, gr. $\frac{1}{4}$, had little effect upon the pain, but 15 mg. of neocaine in 6 c.cm. of cerebro-spinal fluid intrathecally produced complete relief from pain and a flaccid abdomen in five minutes. The patient retched once or twice while the abdomen was being opened, but subsequently went to sleep; a perforation in the posterior wall of the duodenum was closed, and a gastro-jejunostomy was performed under advantageous circumstances. Except for some paralytic

ileus on the second and third days, the patient made an uneventful recovery.

A constant feature in abdominal cases thus anæsthetized is the contracted state of the intestines (except where there is paralytic or obstructive ileus); the abdominal contents not required can be packed away with ease, thus facilitating intra-abdominal manipulations.

LOCAL ANÆSTHESIA IN ABDOMINAL OPERATIONS

In abdominal work local anæsthesia is most useful: (1) in operations not entailing much handling of viscera—*e.g.*, straightforward appendicectomies, colostomy, ventral hernia; (2) in cases where, owing to shock or debility, the patient is a doubtful risk under spinal or local anæsthesia; and (3) in infants. The technique, in outline, consists in:—

(1) Infiltrating the line of the incision by sub- or intra-cuticular injection of 1 per cent novocain, made up with fresh adrenaline, 5 drops to the fluid ounce.

(2) Blocking the cutaneous nerves by a zone of infiltration into the muscle layers, particularly in the neighbourhood of the nerves (intercostal, ilio-hypo-

(3) Anæsthetizing the peritoneum. This is best done after exposure of the transversalis fascia, or posterior sheath of the rectus, when novocain can be injected beneath it, in contact with the peritoneum.

Novocain injected into the mesentery will usually relieve pain due to manipulation of viscera.

The quantity required is usually between 1 and 2 fluid ounces of the 1 per cent solution, but more can be used without danger provided that: fresh, unboiled adrenaline solution is added in the strength mentioned; and care is taken that no appreciable quantity is injected directly into a vein.

A native boy of 9 was admitted with a history of colicky pain in the abdomen, beginning with vomiting 12 hours previously. Examination showed a tumour just above the umbilicus and visible small gut peristalsis. There was faecal vomiting and collapse. After an injection of morphia and local infiltration with 1 per cent novocain, a right paramedian incision allowed a 12-in. intussusception of the jejunum to be delivered and reduced by manipulation. The intussusception had started at a tumour of the gut wall the size of a walnut; this (a lymphosarcoma) was resected, and an end-to-end anastomosis was done at a subsequent operation under a spinal anæsthetic.

GENERAL OPERATIONS

The following notes indicate the general lines of the procedure used.

Abscess.—Many of the smaller types of abscess, and particularly cold abscesses, can be opened almost painlessly through an incision previously injected intracutaneously with 1 per cent novocain. Subcutaneous injections should not be used, as the solution will either enter the abscess cavity, where it will be ineffective, or will be forced into the surrounding zone of hyperæmia, where introduction will be painful and possibly dangerous.

Amputations.—The fingers and toes are easily removed after encircling them with a band of hypodermic injection, a little novocain being introduced more deeply over the line of the nerves. The same method serves for removing ingrowing toe-nails and for opening whitlows, but in the latter case care should be taken not to cause venous congestion by injecting too much of the solution, or pain will result.

For amputating limbs, in addition to the encircling subcutaneous injection, the nerves must be blocked by injecting a considerable quantity of novocain into their neighbourhood or, where practicable (as in the upper arm), by exposing them and injecting the trunks under direct vision. This method is extremely valuable in the emergency amputation of crushed limbs.

Inguinal hernia.—Hernia offers one of the easiest and most useful opportunities for local anæsthesia. After subcutaneous or intracuticular injection of the line of

incision, the needle is introduced at a point about 2 cm. internal to the anterior superior spine and is carried deep to the fascia of the external oblique, and the ilio-inguinal and ilio-hypogastric nerves are blocked with 4 or 5 c.cm. of anæsthetic. Deep injections can then be made round the internal ring, to anæsthetize the peritoneum and cord, or the neck of the sac and genital branch of the genito-crural nerve can be injected after the inguinal canal has been opened.

Hydrocele and varicocele.—These are easily dealt with by (1) injecting the line of incision as described, and (2) blocking the genital branch of the genito-crural and sympathetic nerves by picking up the cord between the fingers and introducing 3 or 4 c.cm. of solution into it.

Tumours of the lower jaw and tongue.—Local anæsthesia here has the enormous advantage of the collaboration of the patient in spitting up blood which would otherwise find its way into the lungs. A preliminary tracheotomy is unnecessary, and the anæsthetist's intrusions are obviated. For the lower jaw one or both inferior dental nerves are blocked by injection of 3 or 4 c.cm. of novocain into the neighbourhood of the nerves as they lie near the lingula on the inner surface of the mandible, the needle being introduced in line with the opposite canine and following the plane of the biting surface of the teeth until the lingula is felt. A hypodermic encircling injection is then made into the face, enclosing the area of the operation.

Hemi-section of the tongue.—This can conveniently be carried out, if the anterior two-thirds only are involved, by blocking both inferior dental nerves as described above, and also the lingual nerves as they lie on the floor of the mouth.

Madura.—The use of local anæsthesia should be confined to the removal of very small early madura, which can be encircled by a hypodermic injection without risk of penetrating the growth. If the injection penetrates, as it easily may in larger growths, the consequent œdema makes differentiation difficult. The larger growths also need a bloodless field only obtainable with a tourniquet, for which general or spinal anæsthesia is necessary.

Skin grafts.—Thiersch grafts are conveniently cut by encircling the area from which the graft is to be taken with a weal of subcuticular injection of 1 per cent novocain.

A native man, 50 years of age, entered hospital with a tumour of three months' duration projecting from the external surface of the left mandible. There was an indurated ulcer on the external alveolus opposite the premolars, and the submaxillary lymphatic glands were enlarged but soft. After removal of the teeth, morphia and hyoscine were injected and the left inferior dental nerve blocked inside the mouth with 5 c.cm. of 1 per cent novocain. A line of subcuticular injection of the same solution was next described round the tumour, and carried forward to the symphysis mentis. Through an incision carried back from the angle of the mouth, and dividing to include the skin adherent to the tumour, the whole mass, together with the body of the mandible from the symphysis to the angle, was removed in one piece. The divided skin and mucosa were sutured. Healing occurred by first intention, and the glands gradually subsided. The growth proved to be an epithelioma invading the bone.

SPINAL ANÆSTHESIA IN GENITO-URINARY OPERATIONS

Spinal anæsthesia is of inestimable value in *suprapubic prostatectomy* on account of (a) the excellent relaxation, (b) the absence of shock and toxic action on the kidneys, and (c) the almost total absence of hæmorrhage due to the fall in blood pressure. If the removal is not done under direct vision and the prostate bed sutured, care must be taken that reactionary hæmorrhage does not follow the rise in blood pressure some hours after operation. In many cases it is advisable

to anticipate this by exerting pressure on the prostate bed by means of a hæmostatic bag or gauze plug attached to a catheter in the urethra to which a weight can be suspended.

LOCAL ANÆSTHESIA IN GENITO-URINARY OPERATIONS

Ligature of hæmorrhoids.—Piles can be satisfactorily ligated under local anæsthesia, which gives better relaxation of the sphincter than even deep general anæsthesia; the relaxation appears to last longer with the former method, thus giving freedom from pain after operation. The anus is first encircled by a weal of subcutaneous 1 per cent novocain. One finger is then placed in the anal canal, and under its direction a needle is passed, at intervals of about 2 cm., deeply into the sphincters and under the anal mucosa, 2 c.cm. being injected at each spot. The needle point should be kept moving so as to avoid injecting into the veins. After a few minutes the sphincter will be found relaxed, and the operation can proceed.

Suprapubic cystotomy.—Either for the removal of calculi, or as a preliminary to prostatectomy, suprapubic cystotomy is easily performed under local anæsthesia provided that novocain can be injected via the urethra. It is particularly useful in the case so often already on the edge of uræmia, in which there has been long-standing prostatic obstruction. Ten to twenty cubic centimetres of 5 per cent novocain with two drops of adrenaline are first injected into the bladder with an ordinary urethral syringe, the bulbar urethra being massaged to pass the solution upwards. A hypodermic weal is next formed along the line of the suprapubic incision with 1 per cent novocain, a little being also introduced beneath the rectus sheath. The bladder is then exposed in the usual way, a further injection being made into the thickness of its wall before it is opened. If the peritoneum has to be stripped up, as is sometimes the case in contracted bladders, it should first be infiltrated with novocain.

Fistula in ano.—This is treated as for hæmorrhoids.

LOCAL ANÆSTHESIA IN EYE, NOSE, AND THROAT OPERATIONS

Many operations on eye, nose, and throat are so commonly performed under a local anæsthetic that no comments are needed. The following, however, may be less familiar.

Trichiasis.—The operation of splitting the inverted lid margin and tarsal plate and inserting into the cleft an epithelial graft from the lip can be done under local anæsthesia as follows. The conjunctival sac is anæsthetized by instillation of cocaine drops at half-hourly intervals thrice in the ward, morphia being given with the third. On the table, the lid affected is injected with 2-3 c.cm. of 1 per cent novocain, a little being also introduced with a fine needle into the conjunctiva of the under side of the lid. The lip which is to provide the graft will also need an injection of 2 or 3 c.cm.

Enucleation of the eye.—This can be done painlessly by injecting 1 or 2 c.cm. of 1 per cent novocain to the neighbourhood of the otic ganglion, the needle being passed inwards along the outer wall of the orbit for a distance of 2 cm. and then a little towards the nasal side. A little solid cocaine may also be placed in the conjunctival sac and, if there is blepharospasm, the lids should be injected with novocain.

CONCLUSIONS

It is emphasized that no originality is claimed for any of the procedures or technique described, all of which are fully described in textbooks of local anæsthesia. Of these, the writer has found Farr's to be the most useful. The intention has been to give a brief account of the type of case found most suitable for spinal and local anæsthesia in a general surgical practice in the tropics.

Reviews

THE PRACTITIONER'S LIBRARY OF MEDICINE AND SURGERY. Volume I:—Anatomy and Physiology. Volume II:—The Technique of Clinical Medicine. New York and London: D. Appleton and Company, 1932. Volume I. Pp. lix plus 1273. Illustrated. Volume II. Pp. xxxiii plus 984. Illustrated. Available from Messrs. Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 37-8 per volume. (The set is to be completed in twelve volumes and Index.)

THE reviewer received these imposing volumes with a sense of grievance, that in these hard times another huge medical encyclopædia should be thrust on to the market. However, he was very rapidly placated, and he is now completely converted to the point of view of the conceivers of this extremely ambitious undertaking, which is no less than an attempt to provide the general practitioner with all the information he can possibly want on any subject connected with his profession, in one set of volumes; we must wish the publishers and editors every success in their venture.

Volume I

This volume is appropriately devoted to anatomy and physiology. In the 676 pages apportioned to anatomy, although there are enough cold anatomical facts recorded to get the student through the average anatomy examination, the physiological and the practical aspects of the subject have been kept in view so that the pages provide excellent reading for the practising surgeon and physician. In the same way the physiological portion, which comprises the other half of the book, really deals with pathological physiology and many of the sections would have supplied excellent introductory chapters to a textbook on pathology. One cannot discuss the individual contributions or contributors, but the latter are all men of established positions in the best-known teaching institutions in the United States. Before concluding our remarks on this volume we must mention the very excellent anatomical illustrations; in these all the various structures are differentiated by the use of colour, and in clarity these 'figures' compare favourably with those in any textbook on anatomy that we have seen.

Volume II

This volume is entitled 'The Technique of General Medicine'. It is a book of nearly a thousand pages, so that the various writers cannot complain that they have had insufficient room to do justice to their subjects. They have, however, not been profligate with their space and in the sections we have had time to peruse we have found each item of technique very completely described without any padding in the form of descriptions of obsolete methods. In the title the word 'medicine' is used not in the general sense but in the special sense, medicine as distinct from surgery; the volume might have been entitled 'Clinical' or 'Diagnostic Methods', though it is more comprehensive than books with these titles usually are. For example, in the chapter on 'The Blood', which covers 160 pages and contains as many words as the average monograph on the subject, there are paragraphs on the origin and development of blood cells, on the histology of the organs of hæmopoiesis, on the functions of the blood cells, on the normal blood count, and on the blood count in different diseases, as well as on the methods by which the various counts and estimations are actually made. An earlier chapter is devoted to physical diagnosis. There are chapters on the bacteriological and serological diagnosis of separate diseases and groups of diseases, on the technique used in the diagnosis of allergic diseases, diseases of metabolism, endocrine diseases, and so forth, on genito-urological diagnosis, on

neurological examinations, and on examination of the eyes, of the ears, nose and throat, and of the mouth. This is of course not a comprehensive list, but it will, we hope, give some idea of the wide scope of this volume.

CHRONIC RHEUMATISM AND THE PRE-RHEUMATIC STATE.—By J. D. Hindley-Smith, M.A. (Camb.), M.R.C.S. (Eng.), L.R.C.P. (Lond.). London: H. K. Lewis and Co., Ltd., 1932. Pp. x plus 144. Price, 5s. 6d.

ON receiving a small book on an everyday medical problem, one's first desire is to classify it. There are a number of classes into which a book of this nature may be placed. It may represent a chapter from a textbook on general medicine by a master of the subject; such books are popular with practitioners nowadays, as they are light and easily slipped into the pocket. It may be a book by a specialist who has a particular theory he wishes to advocate, which is sound enough to be accepted by a section of the profession, but not sufficiently orthodox to be put into a textbook. Finally, there is the book written by the faddist whose views are so unorthodox that no journal will print them. In this instance the name of the publishers is a guarantee that the book is not of the last-named class. We are afraid, however, that we must place it in the second class. Nevertheless, the book contains a well-balanced discussion on the subject, and the author does not over-emphasize his own particular views. Streptococcal vaccines and local treatment of the foci of infection are his sheet anchors, but not to the exclusion of other treatment, such as hydrotherapy. He is quite positive in his statement that the primary focus is *always* in the nasopharynx, but he did not make it clear why he considers that the foci in the bowel and teeth are secondary. He has a very intriguing theory about host-parasite adjustment and/or allergy, which he does not pursue to the extent of boring his readers; he is content to stir their imagination. The author has a curious prejudice against following the usual British custom of italicizing the scientific names of bacteria, and, when quoting another writer who does follow this harmless practice, he goes to the extent of denying all responsibility by inserting 'The italics are his'. A stimulating little book, printed on most excellent paper.

L. E. N.

A TEXTBOOK OF MEDICAL JURISPRUDENCE AND TOXICOLOGY.—By Rai Bahadur J. P. Modi, L.R.C.P. & S. (Edn.), L.F.P.S. (Glasgow). Fourth Edition. Calcutta: Butterworth and Co. (India), Ltd., 1932. Pp. x plus 1003, with 83 illustrations. Price, Rs. 15.

THE present edition of this book is considerably enlarged, and has been revised throughout, with the addition of a considerable number of good original illustrations. New sections have been added on blood-grouping tests, tetra-ethyl lead, carbon tetrachloride, medinal, luminal, naphthalene, trinitrotoluene and quinine. Almost every aspect of medico-legal importance has been dealt with. The book is, on the whole, well written and well arranged, and contains a lot of information which should prove quite useful to students and practitioners in India. There are certain deficiencies which might be remedied in the next edition with advantage. For instance, the ages at which the epiphyses of long bones unite in India are considerably earlier than those in European countries; in some cases this ranges between one and four years earlier. Some work on this subject has been done by Dr. Galstaun, Radiologist, Medical College Hospitals, Calcutta, and could have been included in the book. Again the use of sodium thiosulphate in combating poisoning by arsenic is recognized by all authorities and might be with benefit added in the next edition.

D. A.

A COMPENDIUM OF THE PHARMACOPŒIAS AND FORMULARIES.—By C. J. S. Thompson, M.B.E. Seventh Edition. London: John Bale, Sons and Danielsson, Ltd., 1933. Pp. ix plus 381. Price, 10s. 6d.

THE latest edition of this compendium is, of course, based on the new British Pharmacopœia. It is rather fuller than the average compendium and contains invaluable information on a variety of matters, directly or remotely connected with dispensing and prescribing. There are synopses of thirteen different foreign pharmacopœias, lists of useful non-pharmacopœial prescriptions, of stock mixtures, and of poisons and antidotes, tables of comparative weights and measures, of solubilities, and of boiling and melting points, translations of French, German, Italian and Spanish words commonly used in prescriptions, Latin words and their abbreviations, and so forth; the contents list covers two and a half pages.

The information given is all useful, as far as we can judge it is accurate, and in most cases it is up to date. An exception is the technique that is advocated for the examination of blood for malarial parasites; for this they have given a method suggested by Manson in 1894.

The volume is a handy one, and can easily be slipped into the pocket. We can strongly recommend this compendium to dispensers and practitioners in this country.

THE THEORY AND PRACTICE OF MASSAGE AND MEDICAL GYMNASTICS.—By B. M. Goodall-Copestake. Fifth Edition. London: H. K. Lewis and Co., Ltd., 1933. Pp. xx plus 332, with 118 illustrations (including 22 plates). Price, 12s. 6d.

THIS book, prepared by a teacher of the Chartered Society of Massage and Medical Gymnastics, is an admirable textbook. It embraces the complete syllabus of the Society in the theory of massage and of medical gymnastics, and contains a full description of the surgical and medical conditions treated by massage and movements, with details of their application. The illustrations are clear, helpful, and up to date.

Students in training will find this book very useful; furthermore, those members of the Chartered Society of Massage and Medical Gymnastics in distant parts of the world, where they can get no immediate advice or help, now have a book to which they can turn for reference, and which will keep the aims of the Society and the theory of their work constantly fresh in their minds.

P. B.

ANNALS OF THE PICKETT-THOMSON RESEARCH LABORATORY. Vol. VIII. (The Common Cold.) By D. and R. Thomson. London: Baillière, Tindall and Cox, 1932. Pp. xxiv plus 738, with 51 plates. Price, 63s.

'It is all very well for you doctors to spend your lives investigating rare and interesting diseases, but what you ought to do is to come down to earth and find a cure for the common cold'. This remark, or one of similar purport, has been made to the reviewer not less often than once a month for the last ten years or so, by some normally intelligent layman. Others have probably suffered in the same way. At last he has a formidable answer, and he will no longer have to submit weakly to this platitude. This volume of 738 large quarto pages, of roughly half a million words, and 51 full-sized plates consists of brief résumés of the more important papers that have been written on this subject of the common cold. Every aspect of the subject has been dealt with, and in each section the authors have given their own views. These are always well considered and well expressed, and those who have only a short time at their disposal will do well to seek out these paragraphs. The authors' criticisms are usually very shrewd, as for example when they say that two of the present fashions in medical research are to put everything down to filtrable viruses,

and to carry out a small number of examinations on a very large number of persons, instead of, as they themselves prefer, carrying out a large number of examinations on a much smaller number of persons. However, there is something to be said for fashions, provided that they are not taken too seriously. Every disease of which the causative organism is not known will now be a filtrable-virus disease until it has been proved not to be; it is one way of tackling problems.

The reviewer feels that he must again express his gratitude to the authors of these annals and the patrons of the laboratory from which they are issued each year. They are really splendid gifts to the research workers of the world. Every library attached to a research institution should possess the complete set; fortunately, the back numbers are still available, and the cost to the purchaser is only a fraction of the sum the volumes must have cost to produce.

L. E. N.

FUNGUS DISEASES: A CLINICO-MYCOLOGICAL TEXT.—By H. P. Jacobson, M.D. London: Baillière, Tindall and Cox, 1932. Pp. 317, with 153 illustrations. Price, 3s.

THIS book is a useful compilation of the existing knowledge on mycology in so far as it affects human pathology.

Like many scientific publications from America this book gives the impression that all the most important work on mycology has been done in the United States and that the rest of the world has given a little assistance here and there. This idea is fully borne out in the lists of references at the end of each section. The number of errors in typesetting is rather greater than usual, and amongst the proper names one finds Manson called Mason. In one place treatment is advised as follows '..... beginning with a dosage of five drops Tid.....'. This appears to be a hypercontraction of *Ter in die* and it is hoped this word is only another printer's error and not a new Americanism.

The author has made a new departure in having two introductions written by different people and we feel that the second one might have been better omitted for it begins as follows:—

'The American medical world greets with enthusiasm the appearance of this most important book on "Mycology" by Dr. Henry P. Jacobson'.

This is a rather surprising statement, as it must have been written before the American medical world had the opportunity of greeting the book. It is followed by a rambling statement in which certain outstanding discoveries in medicine are mentioned, practically none of which have anything to do with mycology and appear to have been chosen at random; this remarkable introduction concludes with the following sentence. 'Gratitude is due to him not only from the physicians of both hemispheres but from the countless patients whose suffering will be alleviated by his scientific contribution to all humanity'.

Extravagant language of this kind is likely to prejudice a reader against a book rather than to encourage him in the anticipation of the perusal of a valuable contribution to science.

P. A. M.

AN EMPIRE PROBLEM: THE HOUSE AND VILLAGE IN THE TROPICS.—By D. B. Blacklock, M.D. The University Press of Liverpool. London: Hodder and Stoughton, Ltd., 1932. Pp. 100. Price, 3s. 6d.

THE sub-title of this small volume is somewhat misleading for although health problems of the house and village occupy a considerable portion of the book essays on tropical medicine, the economic importance of maintaining an adequate supply of properly trained medical men in our tropical possessions, and other kindred subjects are also dealt with.

Broadly speaking the lesson conveyed by the book is that disease would be lessened by better housing, sanitation, and pure water supplies in tropical villages.

There is nothing very original in this point of view and many places even in the British Isles could still be found where the same principles might be applied with advantage, as well as in any other part of the Empire.

Although he sets out to discuss the various problems from an empire point of view, the author's horizon appears to have been limited by the West African bush, to judge from the examples of tropical hygiene and pathology that he gives to point his arguments.

AIDS TO DISPENSING.—By A. O. Bentley, Ph.C. Second Edition. London: Baillière, Tindall and Cox, 1933. Pp. vii plus 204, with 10 figures in the text. Price, 3s. 6d.

The second edition of 'Aids to Dispensing' is another welcome addition to the now famous 'Students' Aid Series'. Dispensing is an important art which calls for manual dexterity as well as theoretical knowledge. In this small treatise, the essential requirements of the students going up for their pharmacy examinations are set forth systematically, with special reference to the practical details, and it therefore should be particularly useful.

In India, the importance of having qualified dispensers in pharmacies has not yet been fully appreciated. The present state of affairs is bound to improve in view of the recommendations of the Drugs Enquiry Committee appointed by the Government of India in 1930-31. Books of this type will then be in great demand by students who would like to take up dispensing as a career.

R. N. C.

AIDS TO MATERIA MEDICA.—By G. H. Newns, M.B., B.S. (Lond.), M.R.C.P. (Lond.). London: Baillière, Tindall and Cox, 1933. Pp. vii plus 141. Price, 3s. 6d.

Books of the Students' Aid Series have already gained a good deal of popularity amongst the student community. The reason is not far to seek. Students all over the world want a rapid turnover of the whole subject during the time of the examinations and books of this series have served their purpose efficiently. The recent addition to the series is 'Aids to Materia Medica' by Dr. G. H. Newns and, like its predecessors, this book is likely to be popular.

The book is divided into three parts; part I deals with the common drugs and their composition, preparations, and pharmacological actions; part II deals with the materia medica of inorganic and organic substances including synthetic compounds; sections are included on gland extracts, vaccines, and anti-toxins; and part III consists of a list of preparations, followed by a grouping of drugs according to their pharmacological actions. This part is likely to prove of supreme utility to students. The two appendices are no less useful and contain a valuable list of drugs having doses less than 1 grain.

R. N. C.

DIABETES MELLITUS OR EROTOMANIA.—By M. Vijaya-Raghavulu, B.A., M.B. & C.M. First Edition. Madras: Published by the Gautama Printing Office, 1933. Pp. xiii plus 239. Illustrated. Price, Rs. 5.

We were inclined to believe that the strange title of this book was designed solely to attract the attention of the curious, until we encountered this paragraph in the book itself.

'The one invariable condition I found during my thirty-three years' practice in every diabetic subject of over forty years of age is *excessive sexual indulgence in men and frequent child-birth in women*. One and all of the subjects have evidently excessive internal secretion of testis and ovary and are consequently chronic *erotomaniacs*. To draw pointed attention to the cause, I venture to call the disease *Erotomania* as well'.

The least that one expected from the author was that he would come forward with facts and figures in justification of views which depart radically, as he says,

from those commonly held; yet, beyond a repetition of the same statement in a somewhat more exaggerated form, we find nothing in the book which goes to support it. No further comment on such a book is necessary.

ANATOMY (CATECHISM SERIES). PART II: LOWER EXTREMITY. Fourth Edition, Revised and Enlarged, by Charles R. Whittaker, F.R.C.S.E., F.R.S.E. Edinburgh: E. and S. Livingstone. Pp. 68. Price, 1s. 6d., and postage 2d.

This small book of the Catechism Series deals with the inferior extremity, chiefly on a regional basis, subdividing it into seven parts, viz, the buttock, the popliteal fossa, the thigh, the leg, the sole of the foot, joints and the ossification of bones. The new nomenclature has been chiefly adopted, the old names being mentioned in parenthesis. The relations of the main blood vessels have been nicely shown in tabular form. The unimportant anatomical details have been left out, but the structures and regions of surgical importance, such as the femoral triangle, adductor canal, and the popliteal fossa, have been carefully dealt with in the form of questions and answers. The book will be extremely useful to students for quick revision of the subjects during their examination.

Annual Reports

ABSTRACT OF THE REPORT OF THE LEAGUE OF NATIONS REGIONAL HEALTH CONFERENCE AT CAPE TOWN, SOUTH AFRICA, 15TH TO 25TH NOVEMBER, 1932, BY MAJOR-GENERAL J. D. GRAHAM, C.B., C.I.E., K.H.S., I.M.S. (PUBLIC HEALTH COMMISSIONER WITH THE GOVERNMENT OF INDIA, AND DELEGATE FOR BRITISH INDIA), AND OF THE REPORT OF THE SAME CONFERENCE ISSUED IN THE QUARTERLY BULLETIN OF THE HEALTH ORGANIZATION OF THE LEAGUE OF NATIONS. VOL. II, EXTRACT NO. 1.

The following countries, to the administrations of which invitations had been sent, were represented:

Angola,
Basutoland,
Bechuanaland Protectorate
and Swaziland,
British India,
Kenya,
Gold Coast,
Mozambique,

Nigeria,
Northern Rhodesia,
Southern Rhodesia,
South West Africa,
Tanganyika,
Uganda,
Union of South Africa,
Zanzibar.

The Rockefeller Foundation was also represented.

The main subject dealt with at this Conference was the possibility of the spread of yellow fever by means of motor vehicles and aeroplanes. The general discussion is full of interest but is amply covered by the conclusions which are given below. In addition the statement by General Graham, the representative of the Government of India, is given *in extenso*. He outlined the history of the attitude taken by the Indian Government towards the possible risk of the

introduction of yellow fever into India, laying special stress upon the immense population at risk and upon the difficulty which would be experienced in the eradication of the disease if once established. He pointed out that an aedes survey undertaken at some of the major ports in India before the war revealed a high aedes infestation, and that, owing to the condition of life in large Indian towns, aedes control is exceedingly difficult. Observations published concerning the possibility of protracted incubation periods of the disease in man and of protracted infectivity periods gave further cause for anxiety.

For the above reasons, and to meet the point of view of the Government of India, General Graham stated that the Office International d'Hygiène Publique had altered Article 48 of the Sanitary Air Convention to read as in the present draft, and had recorded their views of its interpretation in their *procès-verbaux*.

The Government of India meantime felt that, although anxious to avoid interference with the ratification of the Sanitary Air Convention, yet, in the light of available information and in accordance with present conditions, prohibition of air traffic from yellow fever areas to susceptible areas was the only reliable safeguard.

General Graham stated that the discussion at this Conference will be of great assistance to the Government of India as defining the concerted action to be taken by the governments of susceptible countries in Africa; but, in view of the possibility of the introduction of yellow fever into the Sudan or East Africa, owing to a break-down in measures taken in any one link of the chain from west to east, the position still required further consideration before the future action of the Government of India could be decided upon.

Conclusions.

(1) None of the fundamental observations upon which public health control of yellow fever is based have been disturbed by recent knowledge. Although under exceptional conditions the incubation period in man may be protracted or the infectivity period may be prolonged, and although experimentally a wider range of dispersal of the mosquito vector has been shown to be possible, yet, for practical purposes, public health control of yellow fever can be based upon the observations that yellow fever is transmitted from actual human cases only in the first three days of the attack, that the incubation period of new cases does not exceed six days, that the agent of transmission is a domestic mosquito which remains in, or in the immediate vicinity of, the house where it has fed, and that the insect, after feeding upon an infected case, must survive for twelve days before it can transmit the virus to another person.

(2) The mouse-brain virus protection test may be accepted as specific for yellow fever.

(3) Large areas in the countries of central, eastern and southern Africa, believed at present to be free from yellow fever infection, must be regarded as infectible.

(4) It is of obvious importance that immediate action be taken to ascertain the position with respect to the presence of the disease, unsuspected, in endemic form, and also to the susceptibility of the population to the disease, in those African countries in which yellow fever has so far been unknown. In these enquiries, the Government of the Anglo-Egyptian Sudan, not represented at this Conference, should be invited to participate. It is satisfactory to record that action recommended in this section is already envisaged in French Equatorial Africa, as well as in Angola; that protection test surveys have already been commenced in the Belgian Congo, and that arrangements are now in progress for similar surveys to be carried out in the Union of South Africa, Bechuanaland Protectorate, South West Africa, Mozambique, Southern Rhodesia, Northern Rhodesia, Tanganyika, Kenya, Uganda and Zanzibar.

(5) Steps should be taken for the provision of equipment and for the training of staff at laboratories in Africa, appropriately selected and situated, where necessary yellow fever work can be carried out after the termination of the detailed work covering many parts of Africa, which is now being undertaken by the Rockefeller Foundation. Such work would include the performance of protection tests and of protective vaccination.

(6) For the purposes of paragraphs 4 and 5 above, the importation of fixed mouse-brain yellow fever virus should be permitted in laboratories in Africa, under Government authority and control.

(7) The co-operation of the Rockefeller Foundation in the establishment of laboratories for yellow fever control advocated in paragraphs 4, 5 and 6 above, in the manner suggested by Dr. Sawyer, is particularly welcome.

(8) The action taken by the British Government in providing facilities in England for protective vaccination against yellow fever deserves attention, and it is hoped that other administrations concerned with public health work in Africa will provide similar facilities at those laboratories where yellow fever work is being carried out or is being projected.

(9) The risk that infection with yellow fever from west to east may spread from village to village by the opening up of new trade and motor routes should be taken into account. It is hoped that the present position along such routes may be determined by protection test surveys of the population, and that the position thereafter may be reviewed from time to time by re-surveys. This slow method of spread of the disease may ultimately prove more capable of breaking down our defences than the more rapid spread which can result directly from modern fast means of transport. In this connection it is suggested that the excellent motor routes which now exist from the French Cameroons across French Equatorial Africa and the northern section of the Belgian Congo need to be considered in connection with risk of infection to the Anglo-Egyptian Sudan and to Uganda.

(10) Although the possibility exists of transport of infected mosquitoes by air, rail or road, it is considered that the greatest risk, or at least the more difficult risk to avoid, consists of the transport of a person during the incubation period of the disease.

(11) It is agreed that the Governments of African countries should be advised forthwith to accept and ratify the International Sanitary Convention for Aerial Navigation, 1932.

(12) The systematic communication of new facts in regard to yellow fever in Africa to the Office International d'Hygiène Publique in Paris, for consideration by its Yellow Fever Commission, is provided for by the above Convention, and this system should be utilized as fully as possible.

(13) Yellow fever control, as now carried out in the West African countries, is an important factor for the protection of neighbouring countries from yellow fever infection, and it is important that these measures should be continued and their efficiency augmented. Special stress is laid upon the provision of pipe-borne water supplies, active destruction of aedes in towns and villages, and the segregation of the non-indigenous population in residential areas in which effective aedes control can be maintained.

(14) The Health Departments of African countries believed at present to be free from yellow fever infection should obtain more information concerning aedes infestation than is now available, and should introduce, or make more effective, measures for the control of aedes in those centres at which risk of introduction of yellow fever infection is specially to be apprehended.

Annex 1 consists of a long address by Dr. W. A. Sawyer, the Rockefeller Foundation representative, in which he dealt with the recent advances in yellow fever

pathology, and as these have already been given in our April issue in the abstract of the Annual Report of the Rockefeller Foundation they are omitted here. His statements about the barriers against the spread of yellow fever are, however, of considerable interest to India so this portion of his statement has been abstracted.

How great is the danger of the extension of yellow fever from West Africa to East Africa and from there to the Orient? It seems highly probable that both these regions are infectible. The mosquito vector, *Aedes aegypti*, is present. Indian and Javanese strains of this species have been shown to be capable of transmitting yellow fever to monkeys by biting. Natives of India are susceptible, for Indian labourers in South America have died of the disease. Daniel Blair reported on an epidemic in British Guiana in 1856 and gave the numbers of cases and deaths in natives of India. The mortality among the Indians was about the same as that among seamen and resident Europeans. Whether the East African negroes would differ from those in West Africa in the degree of their susceptibility to infection with yellow fever or their power to resist the effects of the disease we do not know. The hope that parts of the Orient in which dengue is prevalent might be non-infectible because of cross-immunity between yellow fever and dengue has been taken away by the recent observation of Stefanopoulo and Callinicos that the sera of eleven persons who had recovered from dengue would not protect mice against yellow fever virus.

Since East Africa and parts of South Africa are in all probability infectible, it is important to study the barriers which have protected these regions from invasion during past centuries. The ocean barrier was highly inefficient in the days of the slave trade, when sailing vessels with larva-infected water-butts carried yellow fever back and forth between Africa and the Americas. The voyages by the longer and less frequented route around to the eastern coast of Africa do not seem to have transplanted the infection. Even now the coast-wise shipping may be a factor in the waves of yellow fever which occasionally occur in West Africa, and involve a number of ports. The ocean barrier needs constantly to be reinforced by the rigid suppression of mosquito breeding in ports and on ships.

The barrier to the north of the infected region is a wide band of arid country with a small population, including Mauritania and the Sahara Desert. This barrier has been highly effective against the spread of yellow fever northward. The disease does not infrequently approaches the southern fringe of this arid belt, and Johnson has concluded, on the basis of the studies and experience in Nigeria, that the dry northern country is infectible and able to maintain the infection throughout the year.

The barrier to the south is difficult to discuss, because we do not yet know how far the infected region extends to the south and east of Nigeria. Plans are being made for an immunity survey of parts of French Equatorial Africa and the French Cameroons by governmental health officials and the West African Yellow Fever Commission of the Rockefeller Foundation. Arrangements have been made also for a similar study in the Belgian Congo. There the blood specimens will be collected by governmental health officials and sent to the Commission's laboratory in Lagos for examination. It is hoped that a survey can be made in Angola also. Pending the results of these investigations, we have only the published reports of outbreaks to guide us. As has been previously mentioned, yellow fever has been reported as far south as Angola. Near the southern boundary of Angola and in the northern part of South West Africa there is a region of low rainfall and sparse population which extends far into the interior. It would tend to retard the advance of yellow fever if the disease should be found in the Congo region or northern Angola.

The obvious barrier on the east is the high and mountainous lake region separating the Congo basin from East Africa. A study of the climatic factors which might inhibit the breeding of *Aedes aegypti* in this region and a survey of the prevalence of these mosquitoes in populous places and along routes of travel would give most useful information. It seems improbable that the well-watered equatorial forests of French Equatorial Africa and Belgian Congo, from which yellow fever has never been reported except near the coast, is unfavourable to the spread of yellow fever where the population is adequate. Unknown factors may exist, nevertheless, and a study of the density of *Aedes aegypti*, and the customs of the natives with regard to water storage would be valuable. The region on the boundary between French Equatorial Africa and the Anglo-Egyptian Sudan requires investigation, particularly with regard to the prevalence of the mosquito vector in relation to the density of population.

The possibility that improved methods of travel, particularly by railway trains, motor vehicles, and aircraft, might carry yellow fever through barriers heretofore effective has caused considerable concern. As yet, there has been no evidence that yellow fever has been carried by aircraft in Central or South America. Some of the recent outbreaks in Brazil and Bolivia seem to have been the result of the introduction of non-immune persons, usually troops or refugees from a drought-stricken district, into a region in which most of the people were immune and the presence of a small amount of yellow fever was unrecognized. As soon as the disease becomes actively epidemic in a community and involves many cases, the number of infective mosquitoes and of infected persons travelling during the incubation period may be assumed to rise rapidly. This increase in the carriage of virus into surrounding communities puts a severe test on their resistance to invasion. Epidemics appear in towns which were free of infection or were quietly keeping up a partial immunity of their population by occasional unrecognized infections or small outbreaks. Such it seems to me is the explanation of the extension of yellow fever in Brazil during and after the recent epidemic in Rio de Janeiro, and of the appearance of a succession of epidemics in groups of African towns. Evidently the prevention of epidemics, especially in centres of travel, and the suppression of such outbreaks, when they have been allowed to occur, are essential measures for the protection of infectible places, at a considerable distance. The infected territory cannot be expected to carry the whole burden, however, especially now that the extermination of the disease in Africa seems remote, and the vulnerable regions should protect themselves by making their key cities as nearly non-infectible as possible. In addition, it would be wise to exercise a degree of control over rapid travel from infected to non-infected territory.

That *Aedes aegypti* may survive long flights in aeroplanes has been demonstrated by Griffiths and Griffiths. They drew the conclusions that 'with conditions at airports such as would permit of many mosquitoes getting abroad, it might be expected that approximately one-fifth of the original number would be transported for a long distance—at least 1,250 miles—in one day, with repeated landings and opening of doors, hatches and windows, and refuelling, unloading, and loading taking place'. They were of the opinion that there is no obstacle to the efficient treatment of aeroplanes so as to destroy mosquitoes. The risk of carrying persons in the incubation period of yellow fever seemed to be of greater importance than the transfer of infected mosquitoes.

Protective measures against yellow fever in Africa must be based on a full knowledge of the situation if they are to be effective. The Office International d'Hygiène Publique has urged the extension of the present immunity survey to other regions of Africa. I have mentioned the plans for the Belgian Congo and French Equatorial Africa. In East Africa it would seem

advisable to confirm the supposition that the region is entirely free of infection by taking serum samples from natives in a few representative centres. Health officials in the British Crown Colonies who wish to participate in such an immunity survey can arrange for the laboratory tests through Dr. G. M. Findlay and should send the blood specimens to him at the Wellcome Research Institute in London. He will decide whether to make the tests there or send the specimens on to the Yellow Fever Laboratory in New York.

There are three other annexes by the representatives of the Gold Coast, Angola and Tanganyika Territory describing the conditions in their own particular area. The most striking thing in these statements is the apparent unanimity in regarding motor transport as more potentially dangerous than air transport in spreading yellow fever.

The report ends with a statement on another danger arising from aerial travel which has hitherto received little attention; it is given below:—

TRANSMISSION OF ANIMAL DISEASES BY AEROPLANES

By DR. P. J. DU TOIT

Director of Veterinary Services for the Union of South Africa

When rinderpest swept over South Africa in 1896-97, it was observed that the disease advanced at about the same rate as an ox-wagon. To-day the rate of progress would probably approximate more closely the speed of a motor-car or aeroplane. Vehicular transport has become an important factor in the spread of animal diseases.

One example may suffice to prove the truth of this statement. In August 1918, a dog was smuggled into England from the Continent by aeroplane and was landed at Plymouth. It developed rabies, which spread to seventeen counties, and it was only after a very energetic and costly campaign, lasting three years, that the disease was again eradicated.

South Africa is exposed to this danger in a very special degree, because all aeroplanes entering the Union of South Africa have to pass over tropical countries which harbour many dangerous diseases. Other countries, which are free of these diseases and which lie on the route followed by the aeroplanes, are, of course, exposed to the same dangers. These diseases may be conveyed in three ways: by means of live animals; by means of insect vectors; by means of products containing the infective material.

These three methods may be elucidated briefly.

(a) INTRODUCTION OF DISEASES THROUGH LIVE ANIMALS CONVEYED BY AEROPLANES

At present the danger is practically confined to domestic pets (especially dogs), although in the future the conveyance of larger domestic animals by air may become an everyday occurrence.

Some of the diseases which may be transmitted in this way are the following:

(1) *Rabies*.—This disease has already been mentioned, and measures to guard against the introduction of possible carriers are urgently needed. The long incubation period and the susceptibility of practically all animals (and man) enhance the danger of conveying rabies by air.

(2) *Foot-and-mouth disease*.—The recent, unexplained outbreak of this disease in Southern Rhodesia makes us suspect the aeroplane as a possible carrier of infection. Again, several species of animals (and also man) are susceptible to this disease. In view of the enormous financial burden which an outbreak of this disease imposes on a country, it behoves us to take every possible precaution against its introduction.

(3) *Rinderpest*.—The disease is enzootic in Central Africa, but absent from Southern Africa. Its introduction would be in the nature of a national calamity. In addition to cattle, sheep, goats, and various antelopes

are susceptible; and the transmission of the disease by means of these smaller animals is not beyond the bounds of possibility.

(4) *Lung-sickness (pleuro-pneumonia of cattle)*.—Southern Africa has been free of this disease for many years, although it is prevalent in other parts of Africa.

(5) *Sheep-pox* also is absent from Southern Africa, and its introduction would probably involve the country in very serious expense.

(6) *Hog cholera (swine fever)*.—The European (and American) form of the disease does not occur in South Africa, whereas we have another form of the disease which is also present in other parts of Africa. Recovery from either form of the disease fails to protect against infection with the other. The introduction of the European virus into Africa, or of the African virus into Europe, is therefore liable to cause very serious economic losses.

(b) INTRODUCTION OF DISEASE BY MEANS OF 'INSECT' VECTORS CARRIED BY AEROPLANES

The chief danger lies in ticks. These arthropods, which transmit some of the most important animal diseases, can easily be conveyed on the clothing or luggage (rugs) of passengers travelling by aeroplane. Since infected ticks can live without food for a year or longer, the danger of introducing disease in this way is obvious.

A few examples may be quoted to illustrate the danger.

(1) *East Coast fever (Theileria parva infection of cattle)* has been, or is being, eradicated from some African countries at enormous cost, whereas it remains enzootic in others. The introduction of infected ticks into countries free of the disease would be calamitous.

(2) *Anaplasmosis* is a very fatal disease of cattle. The ticks which transmit it are present in all parts of Africa, whereas the disease itself is absent from many countries (e.g., West Africa). One infected tick could start the disease in such countries.

(3) *Nairobi disease (gastro-enteritis) of sheep* is a virus disease transmitted by ticks which are present over the greater part of Africa. As far as is known, the disease is confined to a comparatively small area in Kenya. But there is nothing to prevent the disease getting a foothold in other countries if infected ticks were introduced.

(c) INTRODUCTION OF DISEASES BY MEANS OF PRODUCTS CONTAINING INFECTIVE MATERIAL

The outbreak of foot-and-mouth disease in the United States of America in 1908 was traced to the introduction of contaminated vaccine lymph. In another instance, hog cholera serum was responsible for the spread of foot-and-mouth disease. The importation of vaccines and sera by air or otherwise should be carefully controlled.

Other objects capable of carrying infection are skins, horns or other parts of animals which air passengers may collect during their travels. The danger of introducing diseases like foot-and-mouth disease in this way is very great.

RECOMMENDATION

Consideration should be given to the desirability of national regulations and international agreements to prevent, as far as possible, the transmission of animal diseases by aeroplanes.

Although this note of Dr. Du Toit applies particularly to the southern half of the African continent many of the points touched upon are of importance to other countries.

ABSTRACT OF REPORT OF A MEETING OF THE ROSS INSTITUTE INDUSTRIAL ADVISORY COMMITTEE HELD ON WEDNESDAY, 1ST FEBRUARY, 1933

SIR MALCOLM WATSON spoke in more general terms on conditions in countries other than India where the Ross Institute is operating.

Dr. Ramsay drew attention to the danger of accepting the behaviour of certain mosquitoes in the laboratory as an indication of what the same species will do in nature quoting examples from his own experience. He then gave an account of the first scheme tried in Assam in the use of atabrin and plasmoquine in prophylaxis of malaria quoting from a letter written by the superintending medical officer who was in charge of the garden where this experiment was carried out.

'After writing to you on the 15th instant, I received a full report from my assistant medical officer about the results of the Blanket treatment with atabrin and plasmoquine, and went up myself to investigate.

'After the fourth day of treatment, three people complained of headache, vomiting and purging, and the passing of red coloured urine, and were kept under observation.

'On the fifth day after the morning dose 11 people were kept under observation with the same symptoms, and three had slight jaundice. Eight of these had a heavy cloud of albumin in the urine.

'The day after the completion of the course, which was Sunday, nine more people were admitted; two of these were suffering from all the symptoms of black-water fever, the urine being of a very dark porter colour, with a slight reddish tinge and the other quite black. Both these, on microscopical examination, showed many red blood corpuscles, renal epithelium and much cell debris. The urine of the other cases varied from an orange colour tinged with pink to light red, dark red to almost black.

'On Monday about 60 people applied for sick leave—the chief complaint being gastric pain. Twenty of these were considered to be malingering and were sent to work, which left matters as follows:—

'Out of a working force of 114 adults and 20 children—134, there were:

Indoor patients	22
Out-patients	40
Attendants	10
				—
				72
				—

'All the cases cleared up rapidly after purgation, except the two apparent B. W. F. cases, and when I had a muster on the Friday following the treatment they seemed to be all right and no complaints.

'The manager had stopped the beginning of plasmoquine until I had investigated the matter, and the first dose of 3×0.01 was given on Friday—six days after the end of the Blanket treatment'.

The dosage is not indicated in the above communication but it is presumably the same as that employed by Dr. Fraser given in his report below. In view of the above alarming report he gave his own investigation the *closest personal supervision*.

The garden on which the experiment was done was seriously affected by malaria in 1921, when it had been black-listed by the government. The spleen rate at that time was about 100 per cent. The mosquitoes causing the malaria came from ravines which intersected the garden in every direction. The ravines were gradually being rendered harmless by permitting the growth of bamboo and other dense forms of vegetation over the streams in these ravines. Oil and Paris-green were still used in places where the shade was not yet effective, but it was hoped in time to create such a growth over all breeding places that malaria would be permanently controlled at no cost by this method. The spleen rate at the end of December 1931 had been reduced to 43 per cent, and this was largely due, he thought, to having let the dense jungle grow, instead of clearing it as had previously been done. The garden had a population of roughly 500 living in compact lines. The garden was fairly isolated, being situated rather more than half a mile from the nearest habitation.

The spleen rate of children on 13th September, 1932, was 56 per cent (middle of transmission season). The total parasite rate immediately prior to treatment, 52 per cent. The gametocyte rate prior to treatment was 12 per cent.

Commencing from 19th September, atabrin was given for five days in doses of one tablet in the morning and two tablets in the evening (each tablet 0.1 gramme), and proportionately for children.

The slides of the gametocyte carriers only were taken after atabrin (but before plasmoquine), and showed a disappearance of benign tertian, but a persistence of quartan and malignant gametocytes, particularly the latter.

A treatment of plasmoquine was then given for five days from 25th September. The parasite rate taken shortly after the atabrin-plasmoquine treatment was 11.5 per cent. There was only one gametocyte found.

Subsequent anti-gametocyte treatment beginning 6th October was given to the whole population on two consecutive days a week for eight weeks, with a view to preventing the spread of infection, and all cases of active malaria occurring after the initial treatment were re-treated until free from parasites.

On 27th December, 1932, three months after the beginning of treatment, the spleen rate in children was 26 per cent. Special points as regards treatment were:—

Plasmoquine was given after food during the treatment, and in doses of 0.01 gramme twice daily for adults.

On the fifth day of plasmoquine treatment, 0.01 gramme and 0.02 gramme were given morning and evening respectively. Proportionate doses were given to children. In the subsequent anti-gametocyte weekly mass treatment, plasmoquine was given irrespective of meal-times. Weakly or anemic cases were treated in hospital. *There were no complications, either with atabrin or plasmoquine.* In fact, the coolies were very enthusiastic about the treatment.

The immediate results of this experiment have been very satisfactory. Although, however, the garden lent itself admirably to the purposes of the experiment, yet it was found that the movement to and from the garden could not be controlled, which is essential if the population is to be kept free from infection; there was also difficulty in getting all people who developed a temperature subsequently to present themselves for blood examination. From the parasite rates shown there was an immediate failure rate of over 21 per cent. In addition, there were 50 cases of malaria from 19th September to 31st December; many of these, no doubt, were relapses, but many, especially the later cases, were in the opinion of the investigator reinfections. It appeared, too, that many cases were refractory to atabrin, even when the dose was increased by one-half for six days.

The position now is, however, that malaria has been reduced to a very low level amongst the human population and also in the mosquito population. Whether it will continue at this low level by the treatment of individual infections cannot be said. There will be a new survey at the beginning of next transmission season, and it will be decided whether the treatment be repeated or whether the results of that just given should continue to be observed. The treatment of this population cost nearly Rs. 2,000, which it was agreed should be paid partly by the Ross Institute, and partly by Messrs. Bayer. It cost over Rs. 3 a head, but the makers hope to reduce this to about Re. 1, partly by getting the government to remove the 25 per cent import duty on the drug, as is done in the case of quinine.

It will be seen from this experiment that it is still too early to draw any final conclusion as to the possibility of eliminating malaria or keeping it at a permanently low level by means of atabrin and plasmoquine.

Dr. Manson also described some experiments with these drugs but his work is not sufficiently advanced to allow him to express an opinion.

Both Drs. Fraser and Manson after giving anti-dysentery bacteriophage an extensive trial are very definitely of the opinion that it is valueless in treatment.

Correspondence

ASSOCIATION OF MEDICAL WOMEN IN INDIA

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—The undernoted resolution was passed at a meeting of the Northern Division of the Association of Medical Women in India, and later was adopted by the Council of the Association.

'In the opinion of this meeting the time has come for reconsidering the allotment of Medical Women for work in India. The efficiency of the work would be enormously increased if there were groups of medical women working together, each being a specialist in her own subject, e.g., surgery, medicine, gynaecology and obstetrics, and pathology. In this way there would be centres of highly organized work in large cities where (a) surrounding dispensaries could refer their more serious cases for treatment; and (b) post-graduate work could also be carried on. These centres might employ honorary workers in addition to the paid staff of specialists'. The reasons given in the discussions which led to the resolution were as follows:—

Medical work in most hospitals in India at the present time is not up to the same standard as in Europe. The reason for this is partly that medical officers have no time to carry on careful and detailed clinical and pathological examinations, and partly that medicine has now become so highly specialized that one or two doctors cannot hope to be experts in all departments. Under the present system where one medical woman is in charge of a small hospital with one qualified assistant, or even where two medical women are in charge of a larger hospital with two or more assistants, it is impossible to keep pace with the many new methods both for diagnosis and treatment. We lose many opportunities of successful treatment, and each time we lose the confidence of a patient. In some towns there are two or three hospitals, each of which may be poorly equipped and all of which are poorly staffed according to modern ideas. These hospitals have done excellent pioneer work and have gained the confidence of the public, but no one knows better than the doctors in charge that very much better work might be done, and very much greater success attained, if the doctor had more leisure for thought and study, and especially if they were able to concentrate on one department of the work and refer other cases to colleagues specially trained to receive them. The need being so clear we feel the time has come to put the matter forward, and to try for a complete reorganization of medical relief in India, or at least in the smaller towns and districts, for the system we are advocating exists to some extent in the larger towns and teaching institutions.

No doubt there would be difficulty at the present time in getting additional expenditure met, but would it not be possible for different charitable organizations to close down neighbouring institutions, and pool all their resources on one institution organized in the manner indicated above. A chain of dispensaries through the surrounding district would keep in touch with the hospital. In the end more good would be done even if a smaller number of in-patients were treated.

Although our discussion related chiefly to women's hospitals, there is no doubt that similar reorganization is equally needed for men's hospitals.

Yours, etc.,
RUTH YOUNG,
President.

VACCINATION AGAINST SMALLPOX

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—On p. 242 of your issue of April 1933 appears a letter regarding 'Vaccination against Smallpox', with a note in reply thereto by Lieutenant-Colonel A. D. Stewart, I.M.S., to which I should like to add one or two comments.

Firstly, is it not possible that, when a tube of lymph is assessed as sufficient for 4 persons, the manufacturers have gauged the amount necessary for use by the clumsiest vaccinator with the worst technique?

Secondly, I would make a plea in favour of more attention being paid to the finer points of vaccination technique at schools of instruction. With ample opportunity for noting methods and results of vaccinations done in different parts of India, we have found them to vary in appearance from pin-pricks to attempted amputations, and we have also been struck by the diverse methods employed. The object of vaccination is to split the epidermis and to inoculate the virus no deeper than the region of the stratum granulosum and stratum Malpighii.

In some parts of India vaccinators scarify the arm, and then when it is nice and bloody they mop on the lymph through the oozing mess; the result, apart from possible sepsis, is that nothing happens, for the lymph is either washed away in the gory stream or so diluted as to be ineffectual. For this reason I object to the circular drill seemingly approved in the last paragraph of Colonel Stewart's note.

In highly skilled hands the drill may possibly be successful, but I submit that it can never be as good as a cutting edge or point. For manufacturing reasons the edge of the drill must be relatively broad so that on circular scarification a ditch is produced rather than a split, and, whereas the latter, on swelling, closes over the inoculated virus, the former in comparison is flushed by oozing serum from the bottom and sides, and the virus stands relatively less chance of establishing itself.

The truth of this assertion has frequently been suggested by the success of lancet-scarification after drill-vaccination has failed.

Dr. A. E. Cope, of Westminster Hospital, used to teach that a good vaccination should after a minute or two show only the minutest blood speckling along the lines of scarification and that no drop of blood should flow.

A few years ago an overseas port was infected with smallpox, and vaccination with drills produced a regrettable number of failures. The drills were scrapped, lancets imported, and demonstrations in technique given to the specially enrolled vaccination staff who were taught to put three small beads of lymph, each about the size of millet seed, spaced vertically upon the cleansed skin, and to vaccinate *through* these with only 3 or 4 vertical parallel scarifications each about $\frac{1}{4}$ inch long. The result was a most satisfactory crop of successes, practically no sepsis, phenomenal popularity of vaccination inasmuch that some who applied for vaccination were found to have been done already on the other arm or leg (presumably vaccination certificates were proving to be of marketable value), and cessation of the epidemic, if I remember aright, within about 6 weeks.

It is true that, in a population of about 58,000, about 78,000 vaccinations were performed which suggested that both the population and the vaccinators meant to do the thing properly, but I still maintain that it was the latter's technique to which the success was due; it was found that, with a tube estimated by the manufacturers as sufficient for 10 persons, between 30 to 42 persons could be satisfactorily vaccinated, according to the lightness of touch of the vaccinators of whom, strangely enough, a Somali girl proved to be the best.

Yours, etc.,
C. L. B.

BOMBAY,

THE OCCURRENCE OF HÆMOGLOBINURIA DURING TREATMENT OF MALARIAL FEVER WITH ATEBRIN AND PLASMOQUINE

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I was interested to read in the last (March) issue of the *Indian Medical Gazette* the article of Drs. Banerjee and Brahminchari on the occurrence of hæmoglobinuria during treatment of malarial fever with atebrian and plasmoquine, as a similar case passed through my hands in November last.

As I am beginning to feel that there is some connection between the hæmoglobinuria and plasmoquine, I am narrating below the case which was attended by me.

A young college student started getting fever in the beginning of October 1932. He was treated with quinine and the fever left him in five or six days. In the last week of October 1932 again he started getting fever; he was similarly treated with quinine, but to no effect. He was therefore put on plasmoquine compound tablets, one pill thrice daily. Three days after the administration of plasmoquine the patient passed a large amount of hæmoglobin in his urine, his skin became dark and the eyes jaundiced. He was diagnosed to be a case of blackwater fever. Plasmoquine was therefore stopped. He was treated with alkalies and blood transfusion, followed by intravenous glucose and citrate, without improvement. The patient ultimately died on the third day after the appearance of hæmoglobinuria.

Fortunately, some pills out of the phial of plasmoquine were left over; these I passed on to the Professor of Pharmacology in the Medical College here. He experimented with them on dogs, but could not detect any toxicity in the drug.

During the last autumn another two cases of blackwater fever occurred here and in each one of them the hæmoglobinuria appeared after the administration of plasmoquine. Suspicion has therefore been aroused in one's mind, does plasmoquine play any part in the causation of hæmoglobinuria? Though on the other hand hundreds of cases of malarial fever have been treated with plasmoquine without any untoward effects.

Yours, etc.,
GOPAL SINGH CHAWLA,
CAPTAIN, M.D., B.S.

LAHORE,
23rd March, 1933.

ANTI-RABIC TREATMENT

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—Can anti-rabic treatment be carried out in remote villages without sending the patients to anti-rabic centres?

A search through literature tells us that nowadays anti-rabic vaccine can be sent out in ampoules to different parts of the country, thus doing away with the necessity of maintaining centralized anti-rabic institutes.

Is the potency of the vaccine affected in any way during transit and storage at the ordinary room temperature?

How long is its potency maintained when it has left the laboratory?

Now provided its potency is maintained, from what sources may we obtain a supply of the vaccine at a minimum cost?

As, at present, it is not available from the ordinary druggist's shop, so we must look to some anti-rabic centre such as Shillong or Calcutta for its supply.

Yours, etc.,
A. K. GHOSE, L.M.F., L.T.M.,
Medical Officer.

AMBARI TEA ESTATE,
CARRON P. O.,
JALPAIGURI.

[Note.—We submitted Dr. Ghose's letter to Dr. M. J. Nicholas who is in charge of the Pasteur Institute at the Calcutta School of Tropical Medicine; he kindly supplied the following information:—

'Anti-rabic treatment cannot be carried out in remote villages because no facilities exist in these places for the administration or storage of the vaccine. Most provinces have now established treatment centres at District Headquarters hospitals where treatment is available for patients from the surrounding villages. Arrangements for such a scheme are in progress in Bengal at present.

The potency of the vaccine is not affected during transit, but it should be stored in a cool place and not at ordinary room temperature.

When stored in the cool and screened from light the vaccine retains its immunity for a period of four months from date of manufacture.

The source of supply is from the Pasteur Institute of the Province.

The reason why anti-rabic vaccine is not sent out from Calcutta at present is because no facilities exist for the bottling of the vaccine in ampoules, and the only safe method of sending out vaccine is in ampoules'.—Editor, I. M. G.]

A LEECH IN THE NASAL CAVITY AND ITS REMOVAL

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—On page 212 of your issue of April 1933 appears a note entitled 'A Leech in the Nasal Cavity and Its Removal', which prompts me to draw attention to a method of dealing with the situation which may not be generally known, but upon which I stumbled by accident in Bakloh some years ago. An Officer of the local regiment brought to me his spaniel which had been afflicted for some days with a leech in the nose. We tried the water treatment, but the leech retracted up again when touched by the forceps, and nasal lavage with saline appeared to disturb the dog more than the leech! All efforts at holding the animal still having proved ineffectual, I gave him a few whiffs of chloroform, and long before the dog showed signs of going under, the leech lay limply in the animal's nostril and was easily withdrawn.

I recommended this method to a friend in Burma some years later, and it was tried with equal success. If therefore leeches are so susceptible to chloroform, perhaps administration through a Junker or similar apparatus, up the affected nostril in human beings would be equally successful?

Yours, etc.,
C. L. B.

BOMBAY,
25th April, 1933.

ANTIPHLOGISTINE SUBSTITUTES

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—Regarding the note on Antiphlogistine substitutes in your paper last month (March 1933), I beg to record my experiences.

I have an ample opportunity of testing the efficacy of various antiphlogistic plasters in various diseases, on the students in the Gurukula Kangri, an educational institution. More than 600 students reside in the boarding house.

All the Indian preparations that I tried are lacking in the power of retaining heat for more than one or two hours; on the other hand the American preparation, Antiphlogistine, retained its heat for about 6 or 7 hours. My patients suffering from acute pharyngitis and tonsillitis always complained of the Indian preparations feeling very cold in the morning after applications at night. This is also my own experience.

The second point of difference is that the Indian preparations are either too hard to stick to the lint and

have no hygroscopic power, or they are not properly dehydrated. A chemist friend of mine informs me that the hygroscopic quality does not depend merely on putting glycerine in the preparations, but that they require dehydration by proper chemical methods. A patient of mine told me that he softened the hardened mass of an Indian preparation by putting in some water; this is still worse as the water evaporates and leaves the plaster as hard flat pieces on the skin which fall down from underneath the piece of lint.

The only drawback in the use of the American preparation is its price which is about two and a half times the price of the same bulk of the Indian

preparations. If the Indian manufacturers can improve their stuff, and satisfy both the physician and the patient, there is no doubt that there would be a big demand for their products.

Yours, etc.,

RADHA KRISHNA GROVER, B.Sc., M.B., B.S.,
Chief Medical Officer.

GURUKULA RESIDENTIAL
UNIVERSITY,
GURUKULA KANGRI (HARDWAR).
30th March, 1933.

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL H. HINGSTON having vacated the post of Surgeon to His Excellency the Governor of Bengal on completion of the term of his appointment, His Excellency has been pleased to make the following appointments:—

(1) Lieutenant-Colonel J. D. Sandes, Professor of Medicine, Medical College, Calcutta, to be Honorary Physician to His Excellency.

(2) Major S. A. McSwiney to be Honorary Surgeon to His Excellency while holding the appointment of Civil Surgeon, Darjeeling.

Lieutenant-Colonel N. C. Kapur, Civil Surgeon, Chittagong, is appointed to act as Superintendent of the Campbell Medical School and Hospital, with effect from the date on which he takes over charge of his duties.

Lieutenant-Colonel P. F. Gow, D.S.O., Professor of Midwifery, Medical College, Calcutta, is appointed to act as Principal of the institution in addition to his own duties, *vice* Lieutenant-Colonel T. C. Boyd.

Lieutenant-Colonel J. C. De, Professor of Clinical Medicine, Medical College, and Second Physician, Medical College Hospitals, Calcutta, is appointed to act as Superintendent of the Medical College Hospitals, Calcutta, in addition to his own duties, *vice* Lieutenant-Colonel T. C. Boyd.

Lieutenant-Colonel J. Morison, C.I.E., Director, Pasteur Institute and Medical Research Institute, Shillong, is appointed to officiate as Inspector-General of Civil Hospitals and Inspector-General of Prisons, Assam, *vice* Colonel J. P. Cameron, C.S.I., C.I.E., who has been granted leave.

Lieutenant-Colonel H. C. Buckley, Civil Surgeon, Lucknow, is appointed to officiate as Inspector-General of Civil Hospitals, United Provinces, with effect from the afternoon of the 25th March, 1933, and until further orders.

Lieutenant-Colonel C. I. Brierley, C.I.E., Chief Medical Officer, North-West Frontier Province, is appointed Inspector-General of Civil Hospitals, North-West Frontier Province, with effect from the 17th February, 1933.

Lieutenant-Colonel M. A. Nicholson, an Agency Surgeon, on return from leave is posted as Chief Medical Officer in Central India and Residency Surgeon, Indore, with effect from the forenoon of the 23rd March, 1933.

Lieutenant-Colonel R. F. D. MacGregor, M.C., an Agency Surgeon, is posted as Residency Surgeon, Hyderabad, with effect from the afternoon of the 30th March, 1933.

Lieutenant-Colonel F. Stevenson, an Agency Surgeon, is posted as Residency Surgeon and Chief Medical

Officer in Baluchistan, with effect from the afternoon of the 21st February, 1933.

Major W. J. Webster, M.C., an officer of the Medical Research Department, is appointed as a Supernumerary Officer at the King Institute, Guindy, Madras, with effect from the 4th March, 1933.

Major R. L. Vance, an Agency Surgeon, is posted as Chief Medical Officer in the Western India States Agency and Residency Surgeon, Rajkot, with effect from the forenoon of the 30th March, 1933.

Major R. S. Aspinall is appointed to be Civil Surgeon, Simla East, with effect from the 1st April, 1933.

Major S. D. S. Greval, an officer of the Medical Research Department, is appointed as a Supernumerary Officer at the Haffkine Institute, Bombay, with effect from the 1st April, 1933, until further orders.

Major B. G. Mallia is appointed as Civil Surgeon, Chittagong, *vice* Lieutenant-Colonel N. C. Kapur transferred.

The services of Major J. Chandra are placed permanently at the disposal of the Government of Bihar and Orissa for employment in the Bihar and Orissa Jail Department.

The services of Captain G. M. Irvine are placed temporarily at the disposal of the Government of Burma, with effect from the date on which he assumes charge of his duties.

The services of Captain B. S. Nat are placed permanently at the disposal of the Punjab Government, with effect from the 10th November, 1932.

To be Captains

Captain (local Major) F. M. Collins, from R. A. M. C. Dated 24th January, 1933, with seniority 1st September, 1929.

Captain C. V. D. Rose, from R. A. M. C., 14th February, 1933, with seniority 25th October, 1922.

To be Captains (on probn.)

P. V. Karamchandani. Dated 13th January, 1933, with seniority 26th February, 1926.

R. K. Misra. Dated 11th January, 1933, with seniority 2nd April, 1926.

K. R. Sahgal. Dated 22nd December, 1932, with seniority 26th September, 1926.

To be Lieutenants

B. A. Porritt, 20th February, 1933, with seniority 26th July, 1930.

M. S. Purvis, 20th February, 1933, with seniority 20th February, 1932.

F. W. Whiteman, 1st February, 1933, and remains seconded.

M. E. Kirwan, 20th February, 1933.

To be Lieutenant (on prob.)

W. S. Morgan, 13th February, 1933.

LEAVE

Colonel J. P. Cameron, C.S.I., C.I.E., Inspector-General of Civil Hospitals and Inspector-General of Prisons,

Assam, is granted combined leave for 5 months, with effect from the 20th May, 1933, or subsequent date from which he may avail himself of it.

Colonel R. McCarrison, C.I.E., K.H.P., an officer of the Medical Research Department on foreign service under the Indian Research Fund Association, is granted combined leave, with effect from the 28th April, 1933, for 6 months and 8 days. His services will be placed at the disposal of the Director-General, Indian Medical Service, from the date on which he proceeds on leave.

Brevet-Colonel G. D. Franklin, C.I.E., O.B.E., K.H.S., an Agency Surgeon, is granted leave, preparatory to retirement, for 6 months and 15 days on average pay combined with leave on half average pay for 9 months and 13 days, with effect from the afternoon of the 30th March, 1933.

Lieutenant-Colonel J. B. Hance, O.B.E., an Agency Surgeon, is granted leave on average pay for 2 months combined with leave on half average pay for 5 months, with effect from the afternoon of the 26th March, 1933.

Lieutenant-Colonel R. B. Seymour Sewell, Director, Zoological Survey of India, is granted leave out of India on average pay for 1 month and 3 days combined with leave on half average pay for 21 months and 8 days, preparatory to retirement, with effect from the 22nd April, 1933.

Lieutenant-Colonel V. N. Whitmore, O.B.E., Civil Surgeon, Simla (West), is granted leave on average pay for three months and 20 days, with effect from the afternoon of the 30th November, 1932, to the 20th March, 1933, inclusive.

Previous notification granting him leave on average pay for 4 months is hereby cancelled.

The notification of February 1933, granting leave to Colonel H. R. Nutt, Inspector-General of Civil Hospitals, United Provinces, is cancelled.

Major J. P. Canteenwalla, Officer in charge, Medical Store Depot, Calcutta, is granted privilege leave from the 18th April to 27th May, 1933.

Major S. D. S. Greval, an officer of the Medical Research Department, is granted leave on average pay for 4 months, with effect from the 15th April, 1933, or the date from which he may avail himself of it.

In supersession of previous notification of the 5th April, 1933, Captain (local Major) F. M. Collins, Surgeon to His Excellency the Viceroy, is granted leave for 3 months and 11 days, with effect from the 7th April, 1933. On the expiry of this leave his services will be placed at the disposal of the Army Department.

PROMOTIONS

Lieutenant-Colonel to be Colonel

W. T. McCowen. Dated 12th February, 1933, with seniority 30th July, 1927.

Lieutenant (on prob.) to be Captain (provl.) (on prob.)
Dev Datt. Dated 10th October, 1932.

RETIREMENTS

Lieut.-Col. G. M. Millar, O.B.E., 24th February, 1933.
Colonel P. L. O'Neill, C.I.E., 28th February, 1933.

Notes

PROFESSOR PICCARD'S EXPERIMENT

Our readers will remember that their balloon ascent to the stratosphere enabled Messrs. Piccard and Kipfer to measure the electrical conductivity of the air and the cosmic radiation intensity in the high atmospheric layers, up to the unbelievable altitude of 16,000 metres.

The next ascent to be effected by Professor Piccard has as aim the completion of these measurements, which had been limited on the previous occasion owing to the very rapid ascension and the dismounting of the apparatus before the descent. These new data will undoubtedly lead to the determination of the exact value of the cosmic radiations as a function of the

altitude, and perhaps even to an understanding of the precise nature of these radiations.

Professor Piccard has taken the precaution to have the principal weldings of the aluminium cabin examined by means of x-rays. The photograph here shown was taken recently in Professor Piccard's laboratory at the Brussels' University. The x-ray apparatus, chosen by Professor

Piccard, is a 'Metalix' portable which can penetrate up to 50 mm. of aluminium with an exposure of a few seconds. The type of apparatus for 180,000 volts which can penetrate 100 mm. of iron, especially designed for metallography, was not deemed necessary. The numerous radiographs of the weldings which surround the two doors of the cabin and the eight vertical supporting bars could be taken with greater facility than would have been the case if a larger instrument had been used, as the apparatus was of the portable type and integrally protected against the high tension and the secondary irradiation emitted by the tube.

WATSON'S MICROSCOPE RECORD

THE last number of Watson's *Microscope Record* has maintained the standard set by its predecessors in providing matter of considerable interest to all microscopists. In this number, no. 28, the Editor has concluded his very practical note on dark-ground illumination. There are a number of diagrams which illustrate the earlier developments of this method, and the note is concluded with a list of instructions for obtaining good dark-ground illumination; these are quite worth copying and distributing to students or laboratory assistants. Other articles are on water-moulds, on the structure of diatoms, and on the fresh-water polyzoa.

One of the microscopes that is described in some detail is what we usually call a 'dissecting microscope', but the use of such an instrument is much beyond the simple dissection of mosquitoes. In many commercial enterprises an instrument of this nature is in daily use. This particular instrument achieves a very high degree of perfection and is in consequence not very cheap, but it appears to be good value for the money; it is priced at £17-10. An extract from the description may be of interest to our readers:—

In textile factories, paper mills, chemical works and in the laboratories of dozens of industries microscopes

of the lowest power are necessary implements. In the prosecution of biological studies related to agriculture, animal husbandry and fisheries a low-power microscope is a daily assistant. In tropical medicine, and especially in connection with work on insect hosts, the use of such a microscope is of vital importance and ministers to the safety of millions of human beings.

This being so, the low-power microscope being so necessary, it is not unreasonable to make it as optically perfect and as practically useful as possible. How is this to be done?

First, it must be a binocular, not only to give comfort to the eyes of the user, but also to provide stereoscopic vision in which objects appear in proper relief.

Also the low-power microscope should provide an erect image so that manipulation or dissection of the object is effected without confusion of movement.

As the erecting binocular low-power microscope is so useful it is an advantage to be able to apply it to a variety of objects. It should be applicable to a large specimen or a small one, therefore it should have a stand with considerable extension and with a clamp to fix it rigidly at the right height. Finally, it may have a change of power effected rapidly, as, for instance, by the revolution of the nosepiece.

All these desirable features will be found incorporated in Watson's low-power binocular microscope; it also possesses a special departure from the Greenough type of instrument in the much more rigid single body with parallel eye-tubes adjustable for width of eyes. This new type of binocular is much more easily adjusted by the observer and is offered as a more practical instrument than earlier types for work on a great variety of objects.

There are, of course, thousands of technologists who ought to have a low-power binocular microscope on their laboratory benches, and doubtless hundreds of these are contemplating the purchase of such an instrument in the near future. May we suggest that they consider the advantages possessed by this instrument.

EPHEDRINE B. D. H.

In Asthma: The vaso-constriction produced in the mucosa by the administration of this drug causes prompt alleviation of the characteristic distressing symptoms (*B. M. J.*, 1930, 1, 873). In fact, results of recent investigation indicate that ephedrine is highly beneficial in the prophylaxis of asthma (*B. M. J.*, 1931, 1, 166) as well as in the treatment of the condition. Moreover, the psychological effect on the patient of the ready availability of a weapon which is known to reduce the severity of the attacks is a matter of no little importance. The effect of a single dose lasts from six to eight hours, so that one dose at bed-time ensures a comfortable night, also a dose during the day enables the patient to undertake prolonged physical effort without undue distress.

In Hay Fever: The unpleasant nasal congestion associated with hay fever, rhinitis, coryza and allied disorders may be subdued almost immediately by the administration of Ephedrine B. D. H. in one or other of its forms as may be suitable to the individual need of the patient. Ephedrine Inhalant B. D. H. (or the Inhalant Compound) being particularly active in reducing the sensitiveness of the mucous membrane.

In Whooping Cough: The benefits resulting from the administration of preparations of ephedrine in whooping cough, especially when complicated with asthma, with asthmatic bronchitis, or with bronchiectasis, have been reported upon; the results of the wide use of Ephedrine B. D. H. Elixir in ordinary clinical practice have confirmed these experimental findings.

Modes of use: Ephedrine B. D. H. is put up in a very large number of convenient forms, i.e., in tablet form for oral and for hypodermic administration, as an elixir, as an aqueous solution in ampoule form, as an inhalant, as a throat spray, and as a nasal jelly.

VITAMINS AND THE MOUNT EVEREST EXPEDITION

THE explorer of to-day realizes the tremendous importance of paying strict attention to the details of his food supply and he looks to it particularly that his provisions are adequate with regard to the essential vitamins.

The members of the Mount Everest Expedition have taken with them Marmite—the yeast extract that is known to be especially rich in vitamin B; they have taken also lemon juice and halibut oil, as sources of vitamin C and vitamins A and D, respectively.

It is obvious that good health, which sufficiency of vitamins ensures, is a vital necessity to members of any expedition if the party is to reach its goal—indeed good health is a vital necessity to every individual whether or not his particular goal be the summit of Mount Everest.

Lack of vitamin B is associated with beri-beri, pellagra, anaemia, skin complaints, constipation, digestive troubles and with many other ills. It is the opinion of many doctors that the majority of people do not ordinarily have anything like enough vitamin B unless they acquire the habit of taking some substance rich in it, such as Marmite. Marmite is taken by the Everest party as a safeguard against these ills—and incidentally it is a pleasant article of food.

Deficiency of vitamin C is responsible for scurvy, a disease that is prevalent among sailors and explorers who do not take with them enough fresh fruit and vegetables.

Vitamin A has been called the anti-infective vitamin, because it appears to play an important part in the prevention of infectious diseases.

Vitamin D is the factor that prevents and cures rickets and other diseases of the bones.

Halibut oil contains both vitamins A and D.

Thus by taking Marmite, lemon juice and halibut oil the Mount Everest party is ensuring against illnesses due to deficiency of vitamins B, C, A and D.

COW AND GATE PRODUCTS

At the All-India Sanitary and Scientific Exhibition held at Madras at the opening of the year, a Gold Medal and a Certificate of Merit were awarded to Cow and Gate, Ltd., of Guildford, England, for their well-known milk foods as exhibited by their agents, Carr and Co., Ltd. The awards were presented by Major-General C. A. Sprawson, C.I.E., V.H.S., I.M.S.

The Exhibition was visited by the Governor of Madras, Sir George Stanley, and over 2,000 medical men from all parts of India called at the Cow and Gate stall.

The awards are undoubtedly a tribute to the care and skill with which the Cow and Gate firm are catering for the special requirements of the Indian market and the increasing demand shows that their efforts to provide their nourishing foods in fresh, safe and perfect condition are appreciated by the public in general.

The importance of pure milk in India both for infants and adults cannot be over-estimated and it is a matter of general regret that actual necessities, such as these foods, should have recently been subject to an increase in the already high customs duties which are imposed upon them.

METALIX 'SENIOR' OUTFIT FOR DEEP THERAPY

We would draw your attention to a phenomenon which might give rise to difficulties when using Metalix shockproof tubes which are equipped with grids on the above-mentioned outfit. Owing to the current characteristics of such tubes the current consumption of the outfit is slightly higher than that of outfits equipped with normal Metalix shockproof tubes. It may happen that the overload relay switches off the outfit after some time. To remedy matters, the overload relay, which

has a high sensitivity, must be made less sensitive by adjusting the lever at the lower end.

It should be borne in mind that in all cases where the overload relay switches off the apparatus, the needle of the milliammeter drops to zero, the cooling pump stops and then the Neon lamp lights up.

When the safety device of the cooling pump is responsible for the switching off of the apparatus, the red lamp lights up first, then the needle of the milliammeter drops to zero and the cooling pump is stopped.

VACUUM-FORMALIN DISINFECTION

RECENTLY, a disinfectant manufacturing company, in order to enlarge their sphere of activities, co-operated with a well-known bacteriologist and after eighteen months of continuous experimentation, during which time a complete disinfectant and a staff for working it were placed at the disposal of the scientist, a large amount of useful data has been obtained.

The data already obtained by scientists was investigated and it was realized that there was scope for further investigation. These further fields were explored, and after much work including extensive tests and careful recording of results not only have useful data been obtained but a great advance in disinfectant design has been achieved.

It was proved that the correct application of heat and gas will effect as satisfactory sterilization as steam, which has hitherto held the field in this type of disinfectant.

Penetration was found to be the great essential for disinfection in this heat-and-gas treatment, just as it is necessary in steam disinfection.

The ingeniously-designed disinfectant, which we show here, has an apparatus connected to the side which, by means of an electrically-driven pump, creates a vacuum inside the chamber.

The necessary heat is obtained by means of steam pipes running longitudinally, the temperature being controlled from outside at will. The heat kills all insects and complete sterilization of the contents is then brought about by the introduction of formaldehyde gas, which, owing to the vacuum, will effectively penetrate all the articles in the disinfectant.

The more complete machine manufactured by the firm is a combined disinfectant which is constructed with the steam process for the use in disinfecting such things as mattresses and heavy clothing, and the new gas system to deal with the lighter articles, such as coloured silks and leather goods, boots, etc. Thus all articles may now be effectively disinfected with the 'Velox' Combined High Pressure Steam and Vacuum Gas

Disinfectant. We believe a more comprehensive and complete machine is unobtainable at the present elsewhere.

The same firm has also devised the 'Velox' Sputum Mug and Flask Sterilizer. Again a great advance has been effected as in this new device each individual mug or flask is washed inside and outside, and after washing a pressure of 15 pounds per square inch of steam is obtained. Owing to the manner in which the articles are washed the sputum is broken up during the washing, and then sterilized.

IODISED MOOGROL (B. W. & CO.)

We have tested this preparation as to its painlessness when given by the intradermal method, comparing it with the standard hydriocarpus esters preparation containing 4 per cent crocote, as used in the leprosy department of the Calcutta School of Tropical Medicine. The two preparations were found to be of equally low irritant value. Iodised Moogrol is, therefore, suitable for injection in leprosy by both the intradermal and the intramuscular routes. As to the therapeutic value of this preparation, this could only be judged after using it in a large number of patients for a number of months or years.

As the preparation is issued by Burroughs Wellcome and Company we have no hesitation in recommending it for a thorough trial in the treatment of leprosy.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

A CASE OF DERMOGRAPHIA WITH A SHORT NOTE ON THE ÆTIOLOGY OF THE CONDITION

By HUGH W. ACTON, C.I.E.

LIEUTENANT-COLONEL, I.M.S.

Director, School of Tropical Medicine and Hygiene
and

DHARMENDRA, M.B., B.S.

Assistant Research Worker, School of Tropical Medicine and Hygiene

Description.—In certain people the skin is hyper-sensitive to mechanical stimuli, such as stroking, scratching, or rubbing. Normally when the skin is firmly stroked with a blunt-pointed instrument a red reaction along the line of pressure is visible 3 to 15 seconds after the application of the pressure. It reaches its height in half to one minute, and fades gradually in a short time. In persons with hyper-sensitive skin the reaction to such a stroke does not stop at the red line, but this red reaction is followed by a local swelling of the skin, i.e., a weal. This condition of the increased susceptibility of the skin to mechanical stimuli is called urticaria factitia or dermographia. As a result of this increased susceptibility letters and words can be written on the skin by scratching with a finger nail or by stroking with a blunt-pointed instrument.

Ætiology.—(1) Both Lewis (1927) and Krogh (1929) put down dermographia to an exaggerated normal reaction of the skin to injury. They believe that all weals, including the factitious weal, are the result of a common chemical substance (which is released by injury to tissue cells) and that the substance exerts a local action upon cutaneous vessels and nerves. The action of this substance is indistinguishable from that of histamine and Lewis called it an H substance. This H substance calls forth the local vascular reaction which terminates in a weal—the triple response of Lewis. This triple response includes, (a) local dilatation of the finest vessels, (b) the flare which is a widespread dilatation of the neighbouring arterioles, and (c) local œdema or weal due to increased permeability of the vessel wall. They contend that the constituent parts of the triple response cannot be attributed directly to the physical stimulus and produce evidence to the effect that a diffusible substance is liberated in the skin which is responsible for the local reaction by its direct effect on the vessel wall and which yields a widespread arteriolar dilatation by acting on a local nervous mechanism. Lewis presents numerous arguments to show that this H substance

simulates histamine more closely than any other substance employed for production of weals. (2) He found that the fluids obtained from the weals of the skin produced by stroking or from small blisters due to burns could stimulate the guinea-pig's uterus to strong contraction, like histamine in great dilution. (ii) Lewis, by producing a large number of these weals on the bodies of patients with urticaria factitia, was able to produce certain constitutional symptoms, such as a rise of cutaneous temperature, flushing of the face, and a slight fall of blood pressure. He argued that the injury at many sites at the same time released considerable quantities of H substance in the wealed areas and that

the constitutional symptoms were due to this substance which had escaped from these areas into the general circulation. Since these symptoms correspond closely to those resulting from subcutaneous injections of minute doses of histamine, he concluded that the action of histamine and H substance were identical. (iii) Harris, working in Lewis' laboratory, showed the presence of a histamine-like substance in alcoholic extracts of human skin. Best, Dale, Dudley and Thorpe (1927) had already demonstrated and isolated histamine from the lung and liver tissue. Barger and Dale (1910) first isolated histamine in pure form from the mucous membrane of the bowel.

Histamine may be in the cell potentially in the form of some inactive precursor, or it may be present in the cell interior, and, being prevented from leaving it so long as the cell membrane is physiologically intact, it produces its action only if some stimulus or injury causes its escape into the extra-cellular fluid.

Krogh quite agrees with Lewis' hypothesis but thinks that the evidence points rather definitely to the existence of at least two substances; one of these is histamine-like or histamine itself, which possesses a relatively small molecule and is readily taken up by the blood through the capillary wall, and the other substance is a colloidal substance of complex nature and of very low diffusibility. Lewis and Krogh both believe that exaggerated reaction to stroking in subjects of dermatographia is not due to increased susceptibility of the mechanism of the reaction to stimulation. Lewis finds that in urticaria factitia the skin is hyper-sensitive to stroking, but if histamine is punctured into the skin the resultant weals are no larger than in controls similarly tested. He argues that if the proneness of urticarial subjects to flare and to weal consists of an unusual reactivity of the vessels, then the stroke and histamine would both be expected to yield exaggerated reaction; in actual experience they do not, response to stroke alone being conspicuous. But our case demonstrates that in urticaria factitia response to histamine is increased. Lewis says that a puncture through solutions of histamine of lower concentration than 1/1,000,000 brings the same result as a puncture through saline. We did not try the puncture test, but in our case the dermal test was positive in a dilution of 1/2,000,000 and lower dilutions were not tried. This result can be compared with the results obtained in 15 asthma patients who were tested up to a dilution of 1/20,000—

8 cases were positive in 1/20,000 dilution,
4 cases were positive in 1/10,000 dilution,
3 cases were positive in 1/8,000 dilution.

So that in our case of dermatographia the reaction to histamine is increased.

Working on the basis that reaction to histamine in dermatographia patients is not increased Lewis concludes that susceptibility of the skin of the urticarial case is really a susceptibility of its cell elements to mechanical injuries, for example, an unusual fragility, or possibly a departure from the usual grade of metabolic stability upon the receipt of these forms of minor damage.

Krogh states that the amount of histamine set free by a given stimulus is evidently very variable and the large variations in susceptibility of individuals and species to different forms of tissue injury are largely to be explained as variations in histamine production and only to a minor, but unknown extent, as variations in reactions to histamine. Thus, to summarize,
